Abstract
This project studies economies with markets for capital reallocation, where gains from trade are driven by firm-specific productivity shocks, but are hindered by search frictions and liquidity considerations. Results are provided on existence, uniqueness and efficiency. The model is tractable enough to analyze monetary and fiscal policy using simple graphs. Additionally, we calibrate it to investigate quantitatively the effects of changes in productivity and credit conditions. The framework can capture several facts deemed interesting in the literature – e.g., capital misallocation is countercyclical, while its price and reallocation are procyclical. We also discuss how well productivity dispersion measures inefficiencies or frictions.

JEL classification: E22, E44

Key words: Capital, Reallocation, Investment, Frictions, Liquidity

1 Introduction

This paper studies economies where capital is accumulated in primary markets and reallocated in frictional secondary markets driven by firm-specific productivity shocks. As motivation, note that efficient economic performance requires getting the right amount of investment over time, plus getting existing capital into the hands of those best able to use it at a point in time, and of course these are intimately related: the ease with which used capital can be retraded affects incentives for the accumulation of new capital, just like the attributes of secondary markets for houses, cars and other assets influence primary markets.

Also note that reallocation is sizable: purchases of used capital constitute 25\% to 30\% of total investment, even ignoring mergers, acquisitions and rentals, and only looking at big, publicly-traded firms (Eisfeldt and Rampini 2006; Cao and Shi 2016; Dong et al. 2016; Cui 2017; Eisfeldt and Shi 2018). Hence, it looks to be important at the macro level. Also, we only concern reallocation across firms, but one could also consider movement of capital within firms (Giroud and Mueller 2015), across sectors (Ramey and Shapiro 1998) or between countries (Caselli and Feyrer 2007). Another reason to study capital reallocation is to see how outcomes depend on fiscal and monetary policy, and one version of our formulation is tractable enough to analyze these policies using simple graphs.\footnote{On fiscal policy, papers showing taxation is crucial for capital formation include Cooley and Hansen (1992), Chari et al. (1994), McGrattan et al. (1997) and McGrattan (2012). On monetary policy, papers studying investment and inflation include Tobin (1965), Sydrauski (1967), Stockman (1981) and Cooley and Hansen (1989), although they use reduced-form monetary models, while we use the microfoundations in the literature surveyed by Lagos et al. (2017). Examples of that literature focusing on capital include Aruoba and Wright (2003), Lagos and Rocheteau (2008), Aruoba et al. (2011), Andolfatto et al. (2016), Shi (1998,1999a,b), Shi and Wang (2006), Menner (2006), Molico and Zhang (2006) and Berentsen et al. (2011).}

One reason to focus on frictional reallocation is that many people argue real-world capital markets are far from the perfectly competitive ideal.\footnote{See Gavazza (2010,2011a,b), Kurman (2014), Ottonello (2015), Cao and Shi (2016), Dong et al. (2016), Kurman and Rabinovitz (2018) and Horner (2018). Note that these are all non-monetary analyses, however, and hence cannot address some key issues in this paper.} Imperfections include adverse selection, financial constraints, the difficulty of finding an
appropriate counterparty, and holdup problems due to bargaining. We downplay adverse selection (on that, see Eisfeldt and Rampini 2008 or Li and Whited 2014) to concentrate on other issues: our secondary capital market features bilateral exchange and bargaining, as in search theory, and the use of assets in facilitating payments, as in monetary economics. In addition to the substantive issue of capital reallocation, our study contributes to the literatures on search and monetary theory.

As additional motivation, consider Ottonello (2015), who compares models of capital with and without search, and argues the former fit the facts better and generate more interesting propagation. Horner (2018) shows vacancy rates for commercial real estate resemble unemployment data, suggesting that search may be as important for capital as it is for labor, and argues that rents on these properties vary considerably, inconsistent with Walrasian theory. In a particular market that has been studied extensively, the one for aircraft, Pulvino (1998), Gilligan (2004) and Gavazza (2011a, b) find that used sales are thrice new sales, that prices vary inversely with search time, and that market thickness affects trading frequency, average utilization, utilization dispersion, average price and price dispersion. This work emphasizes the importance of specificity, making it hard for firms to trade certain types of customized capital, consistent with a search-based approach.

Reallocation moves capital from lower- to higher-productivity firms (Maksimovic and Phillips 2001; Andrade et al. 2001; Schoar 2002). In the specification studied below, productivity differences come from idiosyncratic shocks.\footnote{This contrasts with our previous work on ex ante heterogeneity (Wright et al. 2018), where by assumption some firms cannot trade in the primary market, and hence must get $k$ in the secondary market. Here all firms can get $k$ in the primary market, but might retrade it in the secondary market. This seems more natural and lets us dispense with a few awkward features of the earlier model – e.g., if an agent can only get $k$ in a frictional market, if an opportunity arises in this market he should want to get a lot, but for tractability we had to preclude that by assuming they can store it for just one period.} Conditional on investment, reallocation is efficient iff the nominal interest rate is $\iota = 0$ – the Friedman rule – but investment can be too high or low depending on the tax
rate $\tau$ and bargaining power $\theta$. We prove that $\iota = 0$ implies optimal fiscal policy is $\tau > 0$ for $\theta$ too low and $\tau < 0$ for $\theta$ too high; and that $\tau = 0$ implies optimal monetary policy is $\iota > 0$ both for $\theta$ too low and too high. This is interesting because monetary and fiscal policy are not symmetric, and because it is quite difficult to get $\iota > 0$ optimal in most monetary models.

We show that the model is able to match some observations deemed important in the literature: reallocation is procyclical but mismatch countercyclical (Eisfeldt and Rampini 2006; Cao and Shi 2016); the price of used capital is procyclical (Lanteri 2016); and the ratio of spending on used capital to total investment is procyclical (Cui 2016). However, to match these facts we need to have both increases in productivity and decreases in financial constraints during good times.

Another quantitative findings is that the welfare cost of inflation is quite high due to the way it discourages capital reallocation. We also discuss quantitatively how well productivity dispersion measures misallocation, frictions, or welfare, related to some interesting empirical research.\(^4\)

Also related is much recent work on OTC (over-the-counter) asset markets, including in spirit work following Duffie et al. (2005), but there are major differences.\(^5\) More closely related is the extensive literature on real business cycle theory, where the textbook model is a special case of our model: by shutting down the idiosyncratic productivity shocks, we get exactly the model in Hansen (1985), right down to functional forms. A more recent business cycle model with productivity dispersion is Asker et al. (2014), but that setup has neither a secondary capital market nor liquidity considerations. So, one can say that we

---

\(^4\)See Hsieh and Klenow (2009), Buera et al. (2011), Midrigan and Xu (2014), Cooper and Schott (2016), Ai et al. (2015) and David and Venkateswaran (2017). Our results are broadly consistent with their findings – e.g., Buera et al. (2011) conclude the data is consistent with financial frictions distorting capital across firms, even if self-financing mitigates the problem, which is what our emphasis on liquidity is meant to capture.

\(^5\)First, our asset is neoclassical capital (instead of a Lucas tree) that together with labor produces goods as in standard growth theory. Second, our agents face genuine credit problems that they can address by holding liquid assets. And we do not restrict asset holdings to $\{0, 1\}$, making our setup closer to extensions of Duffie et al. (2005) by Lagos and Rocheteau (2009), Geromichalos and Herrenbrueck (2016) or Lagos and Zhang (2018).
extend modern monetary theory to incorporate capital in more detail, or that we extend mainstream macro to include secondary markets with liquidity, search and bargaining frictions.

Finally, the paper contributes to research on money demand by firms. For older studies of firms’ cash holdings, see Mulligan (1997), Bates et al. (2009) and references therein. More recently, and more closely related to this paper, Rocheteau et al. (2018) develop a model in the New Monetarist tradition, as surveyed by Lagos et al. (2017), except focusing on money demand by firms rather than the usual practice of focusing on households. He and Zhang (2019) have a related model where firms and households both use money; we consider a similar setup in Section 6.1. As in any good monetary model, a fundamental property of the theory presented below is that (some) economic activity decreases with the cost of liquidity, as measured by either inflation or nominal interest rates.

In particular, the model unambiguously predicts that reallocation decreases with inflation or interest rates. As show in Figure 1 (all Figures are at the end), this is consistent with the data. However, we do not make too much of that because it is mainly due to the trend – i.e., the effect is operative at the medium-to long-run frequency, not the standard business cycle frequency. This is not a problem per se, since we are happy to interpret the mechanism in the model as applying mainly in the medium- to long-run, as in Berentsen et al. (2011). Still, there are potentially many reasons why inflation has trended down and reallocation up over the sample, so we do not dwell on it here.

FIGURE 1 ABOUT HERE

In what follows, Section 2 describes the environment. Sections 3 and 4 discuss equilibrium with perfect credit and with money. Sections 5 analyzes a tractable

6The reallocation data is from Computat and inflation from FRED. We use inflation as a benchmark measure of the opportunity cost of liquidity, but the results are similar using AAA corporate bond rates; the T-Bill rate works almost but not quite as well (this may reflect the fact that T-Bills are fairly liquid, if not quite as liquid as cash).
special case. Section 6 presents extensions where, among other things, we use price posting instead of bargaining. Section 7 presents the calibration and quantitative implications. Section 8 concludes.

2 The Environment with Perfect Credit

Time is discrete and continues forever. As shown in Figure 2, at each \( t \) two markets convene sequentially: a frictional decentralized market, or DM; and a frictionless centralized market, or CM. This alternating market structure, adapted from Lagos and Wright (2005), is ideal for our purposes because the CM and DM correspond well to primary and secondary capital markets. In the CM, agents consume a numeraire good \( c \), supply labor hours \( h \) and accumulate capital \( k \) as in standard growth theory. Then in the DM, rather than households trading consumption goods as in most of the related monetary literature, here firms trade capital (even if, for convenience, we sometimes call them households that own firms rather than firms per se). All agents (firm owners) have utility \( u(c) - Ah \), where \( u'(c) > 0, u''(c) < 0 \) and \( u'(c) \to \infty \) as \( c \to 0 \), and discount between the CM and the next DM using \( \beta \in (0, 1) \).

FIGURE 2 ABOUT HERE

We start at \( t = 0 \) in the DM with all agents holding \( k_0 \). Then each firm gets a productivity shock \( \varepsilon \in [0, \bar{\varepsilon}] \) with CDF (cumulative distribution function) \( G(\varepsilon) \). Here the shocks are i.i.d. so that all firms look the same after the CM but before \( \varepsilon \) is realized (Cui et al. 2019 study a version with persistent shocks). This generates gains from trade in the DM, where agents meet randomly in pairs, with \( \alpha \) denoting the exogenous meeting probability. Each meeting is characterized by \( s = (k_b, \varepsilon_b, k_s, \varepsilon_s) \), where \( b \) and \( s \) index the buyer and seller of capital. The CM technology is \( F(k, h, \varepsilon) \) and it is increasing and concave in \( (k, h) \) with continuous second derivatives. It is also increasing in \( \varepsilon \) \( \forall (k, h) \), which means the buyer (seller) in a DM meeting is the one with the higher (lower) \( \varepsilon \). While in principle
F can display CRS or DRS (constant or decreasing returns to scale), we usually impose the latter to make it more likely that, when high and low $\varepsilon$ firms meet, the former gets some but not all the capital.\footnote{As Jovanovic and Rousseau (2002) say, “Used equipment and structures sometimes trade unbundled in that firm 1 buys a machine or building from firm 2, but firm 2 continues to exist. At other times, firm 1 buys firm 2 and thereby gets to own all of firm 2’s capital.” We focus here on cases where it is efficient for high $\varepsilon$ firms trading with low $\varepsilon$ firms to get some but not all the capital; Cui et al. (2019) assume CRS and spend more time on the other case.}

To discuss efficiency, first, firms in the CM hire labor $h = h^*(k, \varepsilon)$ where

$$F_2[k, h^*(k, \varepsilon), \varepsilon] u'(c) = A, \quad (1)$$

given $h > 0$, as follows from standard assumptions. Aggregating this across firms gives total hours, and the time constraint for households, say $h \leq 1$, is assumed slack unless stated otherwise. Next, for capital reallocation, when two firms meet in the DM let $q$ be the amount the one with lower $\varepsilon$ gives to the one with higher $\varepsilon$. If the obvious constraint $q \leq k$ is slack then $q = q^*(s)$ satisfies

$$F_1[k + q, h^*(k + q, \varepsilon_b), \varepsilon_b] = F_1[k - q, h^*(k - q, \varepsilon_s), \varepsilon_s]. \quad (2)$$

With these results on $h$ and $q$ in hand, consider a planner choosing a path for $k$ to maximize utility for the representative agent, subject to search frictions, an initial $k_0$ and resource feasibility after government takes $g_t$ units of numeraire each period. Because the productivity shock is i.i.d., the planner choose the same $k$ for all agents in the CM. The problem can then be written as

$$W^*(k_0) = \max_{k_{t+1}} \sum_{t=0}^{\infty} \beta^t [u(c_t) - Ah_t]$$

st $c_t = y_t + (1 - \delta) k_t - g_t - k_{t+1}$

$$y_t = (1 - \alpha) \int_{0}^{\infty} F[k_t, h^*(k_t, \tilde{\varepsilon}), \tilde{\varepsilon}] dG(\tilde{\varepsilon}) + \alpha \int_{\tilde{\varepsilon} < \tilde{\varepsilon}} F[k_t + q^*(\tilde{s}), h^*[k_t + q^*(\tilde{s})], \tilde{\varepsilon}] dG(\tilde{\varepsilon}) dG(\tilde{\varepsilon})$$

$$+ \alpha \int_{\tilde{\varepsilon} > \tilde{\varepsilon}} F[k_t - q^*(\tilde{s}), h^*[k_t - q^*(\tilde{s})], \tilde{\varepsilon}] dG(\tilde{\varepsilon}) dG(\tilde{\varepsilon}),$$
where \( \delta \) is depreciation, and output \( y_t \) includes production by the \( 1 - \alpha \) measure of firms that did not have a DM meeting, the \( \alpha \) measure that had a meeting and increased \( k \), plus the \( \alpha \) measure that had a meeting and decreased \( k \).

Routine methods yield the planner’s investment Euler equation

\[
rt + \delta = (1 - \alpha) \int_0^\infty F_1[k_{t+1}, h^*(k_{t+1}, \hat{\epsilon}), \hat{\epsilon}] dG(\hat{\epsilon}) \tag{4}
\]

\[
+ \alpha \int_{\hat{\epsilon} > \hat{\varepsilon}} F_1\{k_{t+1} + q^* (\hat{s}), h^*[k_{t+1} + q^* (\hat{s})], \hat{\epsilon}\} dG(\hat{\varepsilon}) dG(\hat{\epsilon})
\]

\[
+ \alpha \int_{\hat{\epsilon} < \hat{\varepsilon}} F_1\{k_{t+1} - q^* (\hat{s}), h^*[k_{t+1} - q^* (\hat{s})], \hat{\epsilon}\} dG(\hat{\varepsilon}) dG(\hat{\epsilon}).
\]

where \( r_t \) satisfies \( 1 + r_t = u'(c_t) / \beta u'(c_{t+1}) \) (in equilibrium this is an interest rate; here \( 1 + r_t \) is just notation for the MRS). While (4) may look like a static condition, it is not, since out of steady state \( k_t \) affects \( c_t \) and \( r_t \). Intuitively, the LHS of (4) is the marginal cost of investment due to discounting and depreciation, while the RHS is the benefit, taking into account shocks and reallocation.

Given \( k_t, k_{t+1} \) and \( q_t, h_t \) and consumption \( c_t \) is given by \( (1 - \delta) k_t + y_t = c_t + k_{t+1} \) and \( u'(c_t) = A/F_2(\cdot) \), where \( F_2(\cdot) \) is the same for all firms since labor is allocated without frictions. One can show the outcome exists uniquely and is summarized as follows:\(^8\)

**Proposition 1** Given \( k_0 \) and the time path of \( q_t \), the solution to the planner’s problem is characterized by (nonnegative, bounded) paths for \( \langle k_t^*, q_t^* (\cdot), h_t^* (\cdot), c_t^* \rangle \), where \( k_t^* \in \mathbb{R}, q_t^*: s \to \mathbb{R}, h_t^*: (k, \varepsilon) \to \mathbb{R}, \) and \( c_t^* \in \mathbb{R} \) satisfy (4), (2), (1) and the constraints in (3).

### 3 Perfect-Credit Equilibrium

While our main interest is in economies with payment frictions, perfect credit provides a natural benchmark. Thus, when firms meet in the DM, the one with

\(^8\)Note that when the definition says paths are bounded, we mean the usual transversality condition for capital, and after adding money the analog for real balances (e.g., see Rocheteau and Wright 2013); we do not dwell on this in what follows.
higher $\varepsilon$ gets $q$ units of capital in exchange for a promise to deliver $d$ units of numeraire in the next CM, where without loss of generality we can restrict attention to one-period debt as long as the constraint $h \in [0,1]$ is slack. Let the CM and DM value functions be $W(a,k,\varepsilon)$ and $V(k,\varepsilon)$, where the CM state includes one’s financial asset position, capital holdings and productivity, while the DM state includes just capital and productivity. In general, $a = z - d - T$ where $z$ is real money balances introduced below, $d$ is debt from the previous DM, and $T$ is a lump sum tax.

The CM problem is then

$$W(a,k,\varepsilon) = \max_{c,h,\hat{k}} \{ u(c) - Ah + \beta\mathbb{E}_{\hat{\varepsilon}} V_{+1}(\hat{k},\hat{\varepsilon}) \}$$

subject to

$$c + \hat{k} = wh + a + \Pi(k,\varepsilon) + (1 - \delta)k$$

where $w$ is the real wage, $\Pi(k,\varepsilon)$ is profit income, and we omit $t$ subscripts when the timing is obvious. From profit maximization, labor demand is

$$\tilde{h}(k,\varepsilon) = \arg \max_{\tilde{h}} \{ F(k,\tilde{h},\varepsilon) - w\tilde{h} \}.$$ (6)

Of course $\tilde{h}$ also depends on $w$, but that is subsumed in the notation, to highlight the dependence on $(k,\varepsilon)$.\(^9\)

Using the constraints, we reduce (5) to

$$W(a,k,\varepsilon) = \frac{A}{w} [\Pi(k,\varepsilon) + a + (1 - \delta)k] + \max_c \left\{ u(c) - \frac{A}{w} c \right\}$$

$$+ \max_{\hat{k}} \left\{ -\frac{A}{w} \hat{k} + \beta\mathbb{E}_{\hat{\varepsilon}} V(\hat{k},\hat{\varepsilon}) \right\}. $$

When nonnegativity constraints are slack, the FOC’s are

$$c : \frac{A}{w} = u'(c)$$

$$\hat{k} : \frac{A}{w} = \beta\mathbb{E}_{\hat{\varepsilon}} V_{1}(\hat{k},\hat{\varepsilon}) \quad (7)$$

\(^9\)Note that labor demand $\tilde{h}$ by a firm does not generally coincide with the supply $h$ of its owner – indeed, with hours traded in the frictionless CM, we do not pin down who works for whom. An interesting extension would be to incorporate frictional labor markets (as Berentsen et al. 2010 or Dong and Xiao 2018 do in similar models, except they do not have capital).
and the budget equation gives labor supply

\[
\bar{h}(\varepsilon) = \frac{wh + a + \Pi(k, \varepsilon) + (1 - \delta)k - \hat{k}}{w}.
\]

The envelope conditions are

\[
W_1(a, k, \varepsilon) = \frac{A}{w}, \quad (9)
\]

\[
W_2(a, k, \varepsilon) = \frac{A}{w} \left[ F_1(k, \bar{h}, \varepsilon) + 1 - \delta \right]. \quad (10)
\]

Assuming an interior solution for \( \bar{h}(\varepsilon) \in (0, 1) \), the following is immediate:\(^{10}\)

**Lemma 1** (i) the CM choice \( \hat{k} \) is independent of \((a, k, \varepsilon)\); (ii) \( W \) is linear in \( a \).

As in the planner’s problem, DM meetings are characterized by \( s = (k_b, \varepsilon_b, k_s, \varepsilon_s) \), and the buyer is the agent with higher \( \varepsilon \). The trading surpluses are

\[
S_b(s) = W[ -d(s), k_b + q(s), \varepsilon_b] - W(k_b, \varepsilon_b)
\]

\[
S_s(s) = W[ d(s), k_s - q(s), \varepsilon_s] - W(k_s, \varepsilon_s),
\]

where the buyer gets \( q(s) \leq k_s \) in exchange for debt \( d(s) \). Simplification yields

\[
S_b(s) = \frac{A}{w} \{ \Pi[k_b + q(s), \varepsilon_b] - \Pi(k_b, \varepsilon_b) + (1 - \delta)q(s) - d(s) \}
\]

\[
S_s(s) = \frac{A}{w} \{ \Pi[k_s - q(s), \varepsilon_s] - \Pi(k_s, \varepsilon_s) - (1 - \delta)q(s) + d(s) \}.
\]

Assuming both parties observe \( s \), one can use a variety of mechanisms to determine the terms of trade; we adopt Kalai’s (1977) proportional bargaining solution (Aruoba et al. 2007 argue that this is has advantages over Nash bargaining in models with liquidity considerations, although here, with perfect credit, they are the same). If \( \theta \) is buyers’ bargaining power, Kalai’s solution sets \((d, q)\) to maximize \( S_b \) subject to feasibility and subject to \((1 - \theta)S_b(s) = \theta S_s(s)\). Given perfect credit, this leads to \( q = q^*(s) \), as in the planner’s problem, and

\[
d^*(s) = \theta \{ \Pi(k_s, \varepsilon_s) - \Pi[k_s - q^*(s), \varepsilon_s] \} + (1 - \delta)q^*(s) \quad (11)
\]

\[
+ (1 - \theta) \{ \Pi[k_b + q^*(s), \varepsilon_b] - \Pi(k_b, \varepsilon_b) \}.
\]

\(^{10}\)Part (i) follows from (8) and part (ii) from (9). As in Lagos and Wright (2005), these use quasi-linear utility, but the same results hold for any utility function that is CRS (Wong 2016), or for any utility function if we assume indivisible labor (Rocheteau et al. 2008).
Before meetings occur in the DM the expected payoff is

\[ V(\hat{k}, \hat{\varepsilon}) = W(0, \hat{k}, \hat{\varepsilon}) + \alpha \int_{\hat{\varepsilon} > \tilde{\varepsilon}} S_b(\tilde{s}) \, dG(\tilde{\varepsilon}) + \alpha \int_{\hat{\varepsilon} < \tilde{\varepsilon}} S_s(\tilde{s}) \, dG(\tilde{\varepsilon}). \]  

(12)

The first term on the RHS is the continuation value from not trading. The second is the surplus from buying capital, where in equilibrium \( \tilde{s} = (\hat{k}, \tilde{\varepsilon}, \hat{k}, \tilde{\varepsilon}) \) and \( \hat{s} = (\hat{k}, \hat{\varepsilon}, \hat{k}, \hat{\varepsilon}) \), because a firm buys when it realizes \( \hat{\varepsilon} \) and meets a firm with \( \tilde{\varepsilon} < \hat{\varepsilon} \). Similarly, the last term is the surplus from selling in the DM. After reallocation, output \( y \) is given by the condition from the planner’s problem except \( \tilde{h} \) replaces \( h^* \). Goods market clearing requires \( c + g + \hat{k} = y + (1 - \delta)k \), and then labor market clearing is automatic by Walras’ Law.

Conserving notation by not carrying around household-specific labor supply and firm-specific labor demand, only aggregate \( h \), we define equilibrium as follows:

**Definition 1** Given \( k_0 \) and time paths for \( \langle g, T \rangle \), a perfect-credit equilibrium is a list of time paths for \( \langle \hat{k}, q(\cdot), d(\cdot), h, c, w \rangle \) such that \( \forall t \): (i) \( (c, \hat{k}) \) solves the CM maximization problem; (ii) \( d(\cdot) \) and \( q(\cdot) \) solve the DM bargaining problem; and (i.i.d.) markets clear.

**Definition 2** Given constant \( \langle g, T \rangle \), a perfect-credit steady state is a time-invariant \( \langle \hat{k}, q(\cdot), d(\cdot), c, w \rangle \) that satisfies the definition of equilibrium except for initial conditions.

With perfect credit, reallocation \( q = q^*(s) \) is efficient, in all meetings, taking as given the parties’ capital holdings. What about aggregate investment? To answer that we need the capital Euler equation, which after a little algebra reduces to

\[
 r + \delta = (1 - \alpha) \int_{0}^{\infty} \Pi_1(\hat{k}, \hat{\varepsilon}) \, dG(\hat{\varepsilon}) \\
 + \alpha \int_{\hat{\varepsilon} > \tilde{\varepsilon}} [\theta \Pi_1(\hat{k} + q(\tilde{s}), \tilde{\varepsilon}) + (1 - \theta) \Pi_1(\hat{k}, \tilde{\varepsilon})] \, dG(\tilde{\varepsilon}) \, dG(\hat{\varepsilon}) \\
 + \alpha \int_{\hat{\varepsilon} < \tilde{\varepsilon}} [(1 - \theta) \Pi_1(\hat{k} - q(\tilde{s}), \tilde{\varepsilon}) + \theta \Pi_1(\hat{k}, \tilde{\varepsilon})] \, dG(\tilde{\varepsilon}) \, dG(\hat{\varepsilon}).
\]  

(13)
By the envelope theorem $\Pi_1 (\cdot) = F_1 (\cdot)$, making (13) look somewhat more like (4) from the planner’s problem. In fact, the first line is the same, while the second is the same iff $\theta = 1$ and the third is the same iff $\theta = 0$.

Heuristically, this can be understood in terms of holdup problems: Bargaining in the DM with $\theta < 1$ increases demand for $k$ in the CM relative to the efficient benchmark, because buying in the secondary market is less attractive when sellers extract part of the surplus. Similarly, $\theta > 0$ decreases demand for $k$ in the primary market, because selling it in the secondary market is less attractive when buyers extract part of the surplus. As in many (not all) bargaining models, there is a $\theta^* \in (0, 1)$ such that these effects net out to deliver efficiency, a version of Hosios (1990). We summarize as follows, with the proof is omitted, because it is a special case of results derived below for monetary economies:

**Proposition 2** *In perfect-credit equilibrium, consumption, hours and reallocation are efficient conditional on investment. Furthermore, there is a $\theta^* \in (0, 1)$ such that investment is too high if $\theta < \theta^*$, too low if $\theta > \theta^*$ and efficient if $\theta = \theta^*$.***

### 4 Monetary Equilibrium

Money is only essential if credit is imperfect (Kocherlakota 1998). Hence we need limited commitment, plus imperfect information so that it is hard to punish those who renege on their obligations by taking away future credit (as in Kehoe and Levine 1983). One way to formalize the relevant information frictions that has proved useful elsewhere (Gu et al. 2013a,b) is this: opportunistic behavior can be observed and communicated to others, and hence the culprit can be punished, with probability $\varphi$. This gives rise to an endogenous limit on unsecured debt, say $\bar{d}$, and if $\bar{d}$ is low there emerges a role for assets in facilitating intertemporal trade; in particular, money is never essential if $\varphi = 1$ but can be if $\varphi < 1$ (Gu et al. 2016). For simplicity, we set $\varphi = 0$, which implies $\bar{d} = 0$ and hence no unsecured credit, although collateralized credit may work.
In particular, one can in principle punish defaulters by taking away future profit as in Holmstrom and Tirole (1998), and taking away existing or newly-acquired assets as in Kiyotaki and Moore (1997). Following the literature, in general, suppose only fractions $\chi_{\Pi}$ of profit $\Pi$, $\chi_{k}$ of existing $k$, and $\chi_{q}$ of newly-acquired $q$ are pledgeable, which means these are the amounts that can be seized after default. For simplicity, we set $\chi_{\Pi} = \chi_{k} = 0$, but with a nod to realism set $\chi_{q} = 1$. Given this, and given that only $(1 - \delta)q$, can be pledged since $\delta q$ depreciates, secured credit is equivalent to a rental agreement: the firm we call the buyer uses $q$ and returns $(1 - \delta)q$ to the one we call the seller. It is equivalent because returning $(1 - \delta)q$ in the CM is equivalent to keeping it and paying off debt with the same CM value. Importantly, note that a cash down payment is always necessary for DM trade: since a seller's opportunity cost of trade is $(1 - \delta)q$ plus the output $q$ generates, if a buyer can only get credit up to $(1 - \delta)q$ he cannot cover that cost without using some cash.

In terms of notation, let $m$ be nominal and $z = \phi m$ real balances, where $\phi$ is the inverse of the CM price level, let DM meetings be characterized by $s = (z_b, k_b, \varepsilon_b, z_s, k_s, \varepsilon_s)$, and let $d(s)$ and $p(s)$ be credit and cash payments. The money supply follows $M_{+1} = (1 + \mu) M$ and the CM government budget equation is $g = T + \phi (M_{+1} - M)$, where $g$ is consumption of $c$ and $T$ is a lump sum tax (transfer if negative), and note that for our purposes it does not matter whether changes in $M$ occur via changes in $T$ or $g$. Inflation is $1 + \pi = \phi / \phi_{+1}$, while $1 + \iota = (1 + r)(1 + \pi)$ is the yield on an illiquid nominal bond and $1 + r = u'(c) / \beta u'(c_{+1})$ is the yield on a on an illiquid real bond. Here an illiquid asset is one that cannot be traded in the DM – thus, $1 + \iota$ is simply the amount of cash in the next CM that makes agents willing to give up a unit of cash in this CM.

\footnote{Getting $q$ on credit supported by $q$ is like getting a house with a mortgage, and Gavazza (2011a) suggests this is realistic in secondary capital markets (although $\chi_{q} = 1$ may be too high; then again it may not, as we show below that a cash down payment is necessary even if $\chi_{q} = 1$). To motivate why $q$ is more pledgeable than $k$, simply imagine that a seller knows the quality of the capital he is selling better than he knows the stuff the buyer holds; see Li et al. (2013) and Lester et al. (2013) for explicit information-theoretic models of pledgeability and acceptability, respectively.}

11
while $1+r$ is the same with numeraire replacing cash, and as always we can price these trades even if the assets do not actually exist. The reason for introducing the notation $\iota$ is this: in stationary monetary equilibrium $z$ is constant, so $\pi = \mu$ and $1 + \iota = (1 + \mu) / \beta$, and therefore it is equivalent to describe monetary policy by $\mu$, $\pi$ or $\iota$. As usual, we impose $\mu > \beta - 1$, or $\iota > 0$, but also consider $\mu \to \beta - 1$, or $\iota \to 0$, which is the Friedman rule.

The CM problem is similar to (5), except the budget equation is now

$$c + \hat{k} + (1 + \pi)\hat{z} = wh + a + \Pi(k, \varepsilon) + (1 - \delta)k,$$

where again $a = z - d - T$, and $1 + \pi$ is the current price of $z$ for the next DM. The key FOC’s are

$$\hat{z} : \frac{A(1 + \pi)}{w} = \beta \mathbb{E}_\hat{\varepsilon} V_1(\hat{z}, \hat{k}, \hat{\varepsilon}),$$

$$\hat{k} : \frac{A}{w} = \beta \mathbb{E}_\hat{\varepsilon} V_2(\hat{z}, \hat{k}, \hat{\varepsilon}),$$

while the envelope conditions are still (9)-(10). The extension of Lemma 1, which again assumes an interior solution for $h \in (0,1)$, is

**Lemma 2** (i) $(\hat{z}, \hat{k})$ is independent of $(a, k, \varepsilon)$; (ii) $W$ is linear in $a$.

The DM trading surpluses are

$$S_b(s) = \frac{A}{w} \{ \Pi[k_b + q(s), \varepsilon_b] - \Pi(k_b, \varepsilon_b) + (1 - \delta)q(s) - p(s) - d(s) \}$$

$$S_s(s) = \frac{A}{w} \{ \Pi[k_s - q(s), \varepsilon_s] - \Pi(k_s, \varepsilon_s) - (1 - \delta)q(s) + p(s) + d(s) \}.$$

In addition to $q(s) \leq k_s$, there are two new constraints, $d(s) \leq (1 - \delta)q(s)$ and $p(s) \leq z_b$. Without loss of generality we can say buyers use all the credit they can get, $d(s) = (1 - \delta)q(s)$, and as argued above, they still need some cash.

**Lemma 3** $q(s) > 0 \Rightarrow p(s) > 0.$
Based on these results, the DM surpluses reduce to

\[
S_b(s) = \frac{A}{w} \{ \Pi[k_b + q(s), \varepsilon_b] - \Pi(k_b, \varepsilon_b) - \hat{p}(s) \} \tag{17}
\]

\[
S_s(s) = \frac{A}{w} \{ \Pi[k_s - \hat{q}(s), \varepsilon_s] - \Pi(k_s, \varepsilon_s) + \hat{p}(s) \} . \tag{18}
\]

Notice \((1 - \delta) q(s)\) and \(d(s)\) cancel in (17) and (18), but that does not make debt irrelevant – it still allows agents to economize on cash, which they like if \(\iota > 0\). As regards \(p(s) \leq z_b\), as usual in these kinds of models, it must bind for at least some \(s\) since, intuitively, \(\iota > 0\) makes cash a poor saving vehicle.

With less-than-perfect credit, the mechanism used to determine the terms of trade matters more. Gu and Wright (2016) show that for any mechanism in a reasonable class: (i) if \(p \leq z_b\) is slack in a type \(s\) meeting then \(q(s) = q^*(s)\) is the same as perfect credit and the mechanism determines \(p(s)\); (ii) if \(p \leq z_b\) binds then the mechanism determines \(q(s) < q^*(s)\). Hence there is a set \(\mathcal{B}\) such that \(p \leq z_b\) binds iff \(s \in \mathcal{B}\), where \(\text{prob}(s \in \mathcal{B}) > 0\). In particular, with Kalai bargaining \(s \notin \mathcal{B}\) implies \(q(s) = q^*(s)\) and

\[
p(s) = (1 - \theta) \{ \Pi[k_b + q^*(s), \varepsilon_b] - \Pi(k_b, \varepsilon_b) \} + \theta \{ \Pi(k_s, \varepsilon_s) - \Pi[k_s - q^*(s), \varepsilon_s] \},
\]

while \(s \in \mathcal{B}\) implies \(p(s) = z_b\) and \(q = q(s)\) solves

\[
z_b = (1 - \theta) \{ \Pi[k_b + q(s), \varepsilon_b] - \Pi(k_b, \varepsilon_b) \} + \theta \{ \Pi(k_s, \varepsilon_s) - \Pi[k_s - q(s), \varepsilon_s] \}.
\]

To define equilibrium, first note that CM consumption and output \((c_t, y_t)\) satisfy the same conditions as above. Goods market clearing is also the same, while money market clearing is simply \(m = M\), and again labor market clearing is automatic by Walras’ Law. Therefore, letting all agents start with \((z_0, k_0)\), we have:

**Definition 3** Given \((z_0, k_0)\) and paths for \((\mu, g, T)\), monetary equilibrium is a list of paths for \((\hat{k}, q(\cdot), p(\cdot), h, c, \hat{z}, w)\) with \(\hat{z} > 0\) such that for \(\forall t\): (i) \((c, \hat{z}, \hat{k})\) solves the CM maximization problem; (ii) \(p(\cdot)\) and \(q(\cdot)\) solve the DM bargaining problem; and (i.i.d.) markets clear.
Definition 4 Given constant \(\langle \mu, g, T \rangle\), monetary steady state is a time-invariant \(\langle \hat{k}, q(\cdot), p(\cdot), h, c, \hat{z}, w \rangle\) with \(\hat{z} > 0\) that satisfies the definition of equilibrium except for initial conditions.

We now derive the Euler equations for money and capital. First, take the derivatives of \(p(\cdot)\) and \(q(\cdot)\) wrt their arguments. Then evaluate these at \(\hat{s} = (\hat{z}, \hat{k}, \hat{\epsilon}, \hat{z}, \hat{k}, \tilde{\epsilon})\), insert them into the derivatives of \(V(\cdot)\) wrt \((\hat{z}, \hat{k})\), and insert those into the FOC’s (15)-(16). For money, the result is

\[
\frac{1 + \pi}{w} = \frac{\beta}{w+1} \left[ 1 + \alpha \int_{\hat{\epsilon} > \tilde{\epsilon}} \Lambda(\hat{s}) dG(\tilde{\epsilon}) dG(\hat{\epsilon}) \right], \tag{19}
\]

where

\[
\Lambda(\hat{s}) \equiv \theta \left[ \Pi_1[\hat{k} + q(\hat{s}), \hat{\epsilon}] - \Pi_1[\hat{k} - q(\hat{s}), \tilde{\epsilon}] \right]. \tag{20}
\]

Using \(w+1/\beta w = u'(c)/\beta u'(c+1) = 1 + r\) and \((1 + \pi)(1 + r) = 1 + \iota\), we get

\[
\iota = \alpha \int_{\hat{\epsilon} > \tilde{\epsilon}} \Lambda(\hat{s}) dG(\tilde{\epsilon}) dG(\hat{\epsilon}). \tag{21}
\]

The nominal rate on the LHS can be interpreted as the marginal cost of carrying cash, while the RHS is the benefit, as one can check that \(\Lambda(\hat{s})\) is the Lagrange multiplier on \(p \leq z_b\), capturing the wedge in monetary exchange. Notice that \(\iota = 0\) implies reallocation \(q\) is efficient, taking \(k\) as given.

For capital, the result is

\[
r + \delta = (1 - \alpha) \int_0^\infty \Pi_1(\hat{k}, \hat{\epsilon}) dG(\hat{\epsilon}) \tag{22}
\]

\[
+ \alpha \int_{\hat{\epsilon} > \tilde{\epsilon}} \Pi_1[\hat{k} + q(\hat{s}), \hat{\epsilon}] \Omega(\hat{s}) dG(\tilde{\epsilon}) dG(\hat{\epsilon})
\]

\[
+ \alpha \int_{\hat{\epsilon} < \tilde{\epsilon}} \Pi_1[\hat{k} - q(\hat{s}), \hat{\epsilon}] \Gamma(\hat{s}) dG(\tilde{\epsilon}) dG(\hat{\epsilon}),
\]

where we define two other wedges,

\[
\Omega(\hat{s}) \equiv \frac{(1 - \theta) \Pi_1(\hat{k}, \hat{\epsilon}) + \theta \Pi_1[\hat{k} - q(\hat{s}), \tilde{\epsilon}]}{D(\hat{s})}. \tag{23}
\]

\[
\Gamma(\hat{s}) \equiv \frac{(1 - \theta) \Pi_1[\hat{k} + q(\hat{s}), \hat{\epsilon}] + \theta \Pi_1(\hat{k}, \tilde{\epsilon})}{D(\hat{s})}. \tag{24}
\]
Notice $\theta < 1$ implies $\Omega(\hat{s}) > 1$, which raises CM demand for $k$ because buying it in the DM is less attractive when sellers extract part of the surplus; $\theta > 0$ implies $\Gamma(\hat{s}) < 1$, which lowers CM demand for $k$ because selling it in the DM is less attractive when buyers extract part of the surplus; and at $\iota = 0$ efficiency obtains at $\theta = \theta^*$, as it does with perfect credit.

What happens at $\iota > 0$? First, higher $\iota$ increases the demand for $k$ in the CM, because buying it in the DM is less attractive when liquidity is more costly, reminiscent of the Mundell-Tobin effect, even if our microfoundations are different. Second, higher $\iota$ decreases demand for $z$, and this reduces CM investment in $k$, because the option value of selling it in the DM is less attractive when there is less cash in the market, reminiscent of the Keynesian notion that lower nominal rates stimulate real investment, even if our microfoundations are again different. Below we discuss which effect dominates. For now, we summarize as follows:\footnote{Apropos the literature, Kurman and Rabinovitz (2018) and the papers cited therein have $k$ holdup problem but no $m$ holdup problem, since they have no money. Papers surveyed by Lagos et al. (2017) have $m$ holdup problems but no $k$ holdup problem, since they have no capital, with exceptions like Aruoba et al. (2011), but there agents trade consumption in the DM, not capital, so our investment channel is missing. Wright et al. (2017) has $m$ and $k$ holdup problems, but the implications are very different since there some agents bring $k$ but not $m$ to the DM while others bring $m$ but not $k$, and here all agents brings both. Hence, that setup is more like the labor market models of Masters (1998, 2011) or Acemoglu and Shimer (1999), where firms invest in physical capital and workers in human capital. This is not a minor technicality: when some agents bring $k$ and others bring $m$, there is no $\theta^*$ that achieves first best with bargaining (although one can achieve it with posting as in Section 6.3 below).}

**Proposition 3** (i) Monetary equilibrium with $\iota = 0$ is the same as perfect credit, and thus efficient iff $\theta = \theta^*$. (ii) With $\iota > 0$ it is never efficient.

### 5 A Convenient Parameterization

Before studying more general versions, consider a specification that delivers sharp analytic results with clear economic intuition. First suppose $\varepsilon \in \{\varepsilon_H, \varepsilon_L\}$, $\varepsilon_H > \varepsilon_L$, with prob($\varepsilon_L$) = $\gamma_L$ and prob($\varepsilon_H$) = $\gamma_H = 1 - \gamma_L$. This implies the bargaining solution is a number $q$, not a function $q(s)$, since there is only one relevant kind of meeting – the kind where someone with $\varepsilon_H$ meets someone with $\varepsilon_L$. Define
Let \( \alpha_H = \alpha \gamma_L \) and \( \alpha_L = \alpha \gamma_H \). Moreover, notice that \( p \leq z_b \) binds in every DM trade, since it must bind in some meetings, and again there is only one relevant kind of meeting. Also, suppose \( F ( k, h, \varepsilon ) = \varepsilon f ( k ) + h \), which is obviously special, but useful because it pins down \( w = 1 \) independent of other variables.

With this structure output is

\[
y = \psi f ( k ) + \xi \varepsilon_H f ( k + q ) + \xi \varepsilon_L f ( k - q ) + h,
\]

where \( \psi = \gamma_L (1 - \alpha_L) \varepsilon_L + \gamma_H (1 - \alpha_H) \varepsilon_H \) is average productivity for firms that do not trade in the DM and \( \xi = \gamma_H \alpha_H = \gamma_L \alpha_L \) is the volume of DM trades. Then the FOC’s from the planner’s problem are much-simplified versions of the general case:

\[
q : 0 = \varepsilon_H f' ( k + q ) - \varepsilon_L f' ( k - q ) \tag{25}
\]

\[
K : r + \delta = \psi f' ( k ) + \xi \varepsilon_H f' ( k + q ) + \xi \varepsilon_L f' ( k - q ). \tag{26}
\]

Now (25) defines \( q = Q ( k ) \) and (26) defines \( k = K ( q ) \), where both are single-valued. We call \( k = K ( q ) \) the IS curve, the standard name for the investment Euler equation; we call \( q = Q ( k ) \) the CR curve, for capital reallocation; and the planner’s solution obtains at their intersection. The slopes of CR and IS are

\[
\frac{\partial q}{\partial k \mid CR} = \frac{\Phi ( k, q )}{\varepsilon_H f'' ( k + q ) + \varepsilon_L f'' ( k - q )}
\]

\[
\frac{\partial q}{\partial k \mid IS} = \frac{\varepsilon_H f'' ( k + q ) + \varepsilon_L f'' ( k - q ) + \psi f'' ( k ) / \xi}{\Phi ( k, q )}
\]

where

\[
\Phi ( k, q ) \equiv f' ( k + q ) f'' ( k - q ) - f' ( k - q ) f'' ( k + q ).
\]

13 Different from the general case, (26) is a static condition: while we still have \( 1 + r = u' ( c ) / \beta u' ( c + 1 ) \), \( w = 1 \) implies \( u' ( c ) = A \) in and out of steady state. Thus we can jump to steady state in one period unless \( h \in [0, 1] \) binds. To see what this entails, consider the case with no DM, a standard growth model with utility and production linear in \( h \). It has a unique steady state \( k > 0 \) where \( c \) and \( h \) solve \( u' ( c ) = A \) and \( h = c + \delta k - f ( k ) \), as long as \( h \in (0, 1) \). If \( k_0 \) is below \( k \) but close, we can jump to \( k \) in one period by setting \( h_0 = \bar{c} + \bar{k} - f ( k_0 ) - (1 - \delta) k_0 \). But if \( k_0 \) is so low that \( h_0 \leq 1 \) binds, the transition has \( h_t = 1 \) for \( t = 1, 2, ... \) until we reach \( k \) such that \( h = \bar{c} + \bar{k} - f ( k ) - (1 - \delta) k \leq 1 \), whence we jump to \( k \). The situation is symmetric if \( k_0 \) is so high that \( h_0 \geq 0 \) binds.
Hence, when they cross, both slope down if $\Phi(k,q) > 0$ and both slope up if $\Phi(k,q) < 0$. Since a few results depend on this, we differentiate cases by highlighting

$$\Phi(k,q) < 0. \quad \text{(Condition F)}$$

While both $\Phi < 0$ and $\Phi > 0$ are possible, as can be shown by example, Condition F holds for common functions like $f(k) = k^n$. It implies that when IS shifts left, e.g., due to an increase in $r + \delta$, both $k$ and $q$ fall, as may seem natural, but is not necessary.

**FIGURE 3 ABOUT HERE**

This is shown Figure 3. Notice in the right panel that the CR curve coincides with the 45° line when $k$ is low, and the solution can occur on this segment. In this situation $q = k$, so when $\varepsilon_H$ firms contact $\varepsilon_L$ firms, the former get all the capital — a takeover. However, we can preclude that with $f'(0) = \infty$. This also precludes $k = 0$, and we can rule out $q = 0$ by having $\iota$ not too big (see below). Given this, the Appendix proves:

**Proposition 4** For the convenient parameterization, CR and IS cross uniquely at $k^* > 0$ and $q^* > 0$.

Moving from the planner’s problem to equilibrium, let us introduce a proportional tax on capital income $\tau$ (we did not do this sooner because the general model is already notationally intense). This changes $\varepsilon f(k)$ to $(1 - \tau) \varepsilon f(k)$ in agents’ budget equation and changes the bargaining solution to

$$\frac{z}{1 - \tau} = (1 - \theta) \varepsilon_H [f(k + q) - f(k)] + \theta \varepsilon_L [f(k) - f(k - q)]. \quad (27)$$

Now, jumping right to the Euler equations, we have

$$\iota = \xi \Lambda(k,q) \quad (28)$$

$$\frac{r + \delta}{1 - \tau} = \psi f'(k) + \xi \varepsilon_H f'(k + q) \Omega(k,q) + \xi \varepsilon_L f'(k - q) \Gamma(k,q) \quad (29)$$
where $\Lambda(k, q)$, $\Omega(k, q)$ and $\Gamma(k, q)$ are the wedges discussed above, written here as functions of $(k, q)$. As in the planner’s problem, (28)-(29) define two curves, but now (28) is actually the LM curve from (some) undergrad macro classes. So we call it that, even if we continue to plot the curves $(k, q)$ space, because those are our key endogenous variables.

Labels aside, existence of monetary equilibrium requires $\iota$ below a threshold $\bar{\iota}$. Uniqueness also requires conditions since there are complementarities at work—i.e., when there is more cash in the market, agents may want to bring more capital, and vice versa. The Appendix proves:

**Proposition 5** For the convenient parameterization, monetary steady state exists iff

$$\iota < \bar{\iota} \equiv \alpha_H \gamma_H \theta (\varepsilon_H - \varepsilon_L) \over (1 - \theta) \varepsilon_H + \theta \varepsilon_L.$$  

It is unique if either $\theta$ is not too small or $\iota$ is not too big.

**FIGURE 4 ABOUT HERE**

As shown in Figure 4, LM starts at $(0, 0)$, lies below the $45^0$ line, and while it is not monotone increasing in general it is under Condition F, which we impose for this discussion. Even under Condition F, however, the slope of IS curve depends on $\theta$, as shown in Figure 4.\(^{14}\) Also shown are the effects of monetary policy. Increasing $\iota$ does not affect IS, and rotates LM clockwise until we hit $\bar{\iota}$, at which point it hits the axis and monetary equilibrium breaks down. For $\iota < \bar{\iota}$, increasing $\iota$ moves us from $a$ to $b$, so $q$ decreases, and $k$ decreases or increases as IS slopes up or down. Hence, at least for some $\theta$, lower nominal rates stimulate real investment, consistent with Keynesian doctrine, but the logic is different: here lowering $\iota$ reduces the cost of liquidity, which facilitates DM trade, and for

\(^{14}\)Heuristically, there are two effects: first, there is less need to bring $k$ from the CM when $q$ is bigger in the DM, and that tends to make IS decreasing; second, higher $q$ means selling capital in the DM is more lucrative, which tends to raise $k$, and that makes IS increasing; and the net effect depends on which is more important, the buying effect or the selling effect, which depends on $\theta$.  

19
low \( \theta \) this raises \( k \) because it improves the option value of selling it in secondary markets. To see the multipliers at work, observe that an increase in \( \iota \) would move us from \( a \) to \( c \) if \( k \) were fixed, but since \( k \) reacts we move to \( b \), attenuating the fall in \( q \) in the left panel and accentuating it in the right.

**FIGURE 5 ABOUT HERE**

Figure 5 shows the effects of fiscal policy. Increasing \( \tau \) shifts IS left but does not affect LM, so \( q \) and \( k \) both decrease regardless of whether IS slopes up or down. To see the multipliers at work, observe that an increase in \( \tau \) would move us from \( a \) to \( c \) if \( q \) were fixed, but since \( q \) in fact reacts, we move to \( b \), attenuating the fall in \( k \) in the left panel and accentuating it in the right. Summarizing the fiscal implications, higher \( \tau \) unambiguously reduces both \( k \) and \( q \). This is different from monetary policy, where higher \( \iota \) unambiguously reduces \( q \), but depending on \( \theta \) can increase or decrease \( k \).

To consider optimal policy, first, note that as in the general model \( \iota = \tau = 0 \) implies \( k \) is efficient iff \( \theta = \theta^* \), but now we have a simple expression for

\[
\theta^* = \frac{\varepsilon_L [f' (k^* - q^*) - f' (k^*)]}{(\varepsilon_H - \varepsilon_L) f' (k^*)}.
\]

(30)

Suppose \( \theta \neq \theta^* \), and let us eliminate the monetary wedge by setting \( \iota = 0 \), to concentrate for a moment on fiscal policy. It is not hard to check that full efficiency obtains at \( \tau = \tau^* \), where

\[
1 - \tau^* = \frac{r + \delta}{\xi \varepsilon_H f' (k^* + q^*) + (1 - \theta \alpha_H) \gamma_H \varepsilon_H f' (k^*) + [1 - (1 - \theta) \alpha_L] \gamma_L \varepsilon_L f' (k^*)}.
\]

One can also check that \( \tau^* \) is decreasing in \( \theta \), which implies the following:

**Proposition 6** For the convenient parameterization with \( \iota = 0 \), optimal fiscal policy is \( \tau = \tau^* \), where \( \tau^* = 0 \) if \( \theta = \theta^* \), \( \tau^* < 0 \) if \( \theta > \theta^* \), and \( \tau^* > 0 \) if \( \theta < \theta^* \). This achieves full efficiency.
As shown in Proposition 2, agents overinvest if $\theta < \theta^*$. Then, the optimal fiscal policy requires $\tau^* > 0$ to reduce investment. Similarly, agents underinvest if $\theta > \theta^*$. Hence, the optimal policy requires $\tau^* < 0$ to encourage investment.

Similarly, suppose $\theta \neq \theta^*$ and let us eliminate the fiscal wedge by setting $\tau = 0$ to concentrate on optimal monetary policy. The Appendix proves the next result, showing how monetary and fiscal policy are not symmetric, in the sense that optimal monetary policy implies $\iota > 0$ for both big $\theta$ and small $\theta$, and generally full efficiency is illusive.

**Proposition 7** For the convenient parameterization with $\tau = 0$, there exist $\theta$ and $\bar{\theta}$, with $0 < \theta \leq \theta^* \leq \bar{\theta} < 1$, such that optimal monetary policy is $\iota^* > 0$ for $\theta > \bar{\theta}$ and for $\theta < \theta^*$. In neither case do we achieve full efficiency.

To understand this, first recall big $\theta$ makes agents underinvest in the CM since they get a good deal buying $k$ in the DM. Higher $\iota$ counters this by taxing the secondary market, raising primary investment and welfare. Then recall small $\theta$ makes agents overinvest in the CM since they get a good deal selling $k$ in the DM. Higher $\iota$ again taxes the secondary market, this time lowering primary investment but raising welfare. Clearly $\iota^* > 0$ is a second-best result: while it mitigates underinvestment for big $\theta$ and overinvestment for small $\theta$, in neither case do we get efficient reallocation, because $q^*$ requires $\iota = 0$.

### 6 Extensions

#### 6.1 Integrated Money Demand

So far, firms (or their owners) hold all the cash to finance secondary capital acquisition. In reality, households also use cash in goods markets, as modeled in many other papers. So consider an economy with two types, entrepreneurs and households, where the former are like the agents in the benchmark model, while the latter supply $h$ and demand $c$ in the CM, but also want a different good $C$ traded among themselves in their own DM (we can instead have them trade with
retailers and get similar results). Households sometimes need cash in their DM for the same reasons that firms need it in theirs. Hence, liquidity will generally be demanded by both firms and households, as in He and Zhang (2019).

Let households have the same preferences in the CM over \( c \) and \( h \). Then as in much other monetary theory, in their DM they get utility \( U(C) \) from a perishable good or service produced on the spot by others at unit cost in terms of disutility. Suppose they match bilaterally at random in their DM, and with little loss in generality suppose there is no direct barter because there are no double-coincidence meetings, only single-coincidence meetings, where one agent likes what his partner produces but not versa. In such meetings each household is a buyer or seller with equal probability. Moreover, we allow perfect credit in some of these meetings, say because the households know each other, while other meetings require money, say because they do not know each other. Let the probabilities of credit and money meetings be \( \sigma_c \) and \( \sigma_m \).

Households’ CM problem is

\[
W^h(a) = \max_{s,h,\hat{z}} \{ u(c) - Ah + \beta V^h(\hat{z}) \} \quad \text{st} \quad c + (1 + \pi) \hat{z} = wh + a
\]

where \( a = z - d - T \). In the DM,

\[
V^h(z) = W^h(a) + \sigma_m \left[ U(C_m) - \frac{A}{w} p_m \right] + \sigma_m \left[ \frac{A}{w} \tilde{p}_m - \tilde{C}_m \right] + \sigma_c \left[ U(C_c) - \frac{A}{w} p_c \right] + \sigma_c \left[ \frac{A}{w} \tilde{p}_c - \tilde{C}_c \right],
\]

where the second two terms on the RHS are surpluses from buying and selling with cash, while the last two are surpluses from buying and selling on credit. In each case, the terms of trade are determined by Kalai bargaining with \( \varsigma \) denoting buyers’ share.

For credit meetings it is easy to verify \( C_c = C^* \) and \( p_c = p^* \), where \( U'(C^*) = 1 \) and \( p^* A/w = (1 - \varsigma) U(C^*) + \varsigma C^* \). For money meetings, \( p_m = z \) and \( C_m \) solves \( z A/w = (1 - \varsigma) U(C_m) + \varsigma C_m \). It is standard to derive households’ Euler equation
$\iota = \sigma_m \lambda(c_m)$, where

$$
\lambda(C_m) = \frac{\varsigma [U'(C_m) - 1]}{(1 - \varsigma) U'(C_m) + \varsigma}
$$

is their liquidity premium. Since the entrepreneur’s problem is the same as before, steady state is determined by

$$
\iota = \sigma_m \lambda(C_m) , \tag{31}
$$

$$
\iota = \alpha_H \gamma_H \Lambda(k,q) , \tag{32}
$$

$$
\frac{r + \delta}{1 - \tau} = \gamma_H \varepsilon_H [\alpha_H f'(k + q) + (1 - \alpha_H) f'(k)] + \gamma_L \varepsilon_L [\alpha_L f'(k - q) + (1 - \alpha_L) f'(k)]. \tag{33}
$$

**Proposition 8** For the convenient parameterization when households use money in goods markets, monetary steady state exists iff $\iota < \max \{ \sigma_m \lambda(0) , \bar{\iota} \}$. It is unique if either $\theta$ is not too small or $\iota$ is not too big. In terms of policy, Proposition 7 is valid as stated.

Notice the system dichotomizes: $C_m$ solves (31), then independently $k$ and $q$ are determined exactly as before. It is known how to break this kind of dichotomy in related models – e.g., make household utility nonseparable between $C$ and $c$, or make $k$ and input to production of $C$. That may well be interesting, but this simple version is certainly convenient because we can study firms’ demand for money without reference to households’ demand for money, hence rationalizing the way we ignored the latter in the benchmark model. In equilibrium, both households and firms use cash if $\iota < \min \{ \sigma_m \lambda(0) , \bar{\iota} \}$, only households use it if $\bar{\iota} < \iota < \sigma_m \lambda(0)$, and only firms use it if $\sigma_m \lambda(0) < \iota < \bar{\iota}$. In particular, if $\iota$ changes due to variation in monetary policy, it is possible to have firms use cash in low- but not high-inflation episodes, while household use it all the time. The money demand of firms and households predicted by our theory is consistent with data, as shown in Figure 6.15

15The vertical axis is money holdings by corresponding entities normalized by nominal GDP. All data are from FRED. For the money holding data of the households, we use the checkable deposits and currency data of the households. For that of the firms, we use the checkable deposits and currency data of non-financial business.
6.2 A Somewhat Convenient Parameterization

In the interest of utmost tractability, in Section 5, \( \varepsilon \in \{\varepsilon_L, \varepsilon_H\} \) and \( F(k, h, \varepsilon) \) is linear in \( h \). We now show the method works, if somewhat less easily, if we relax the second restriction by using \( F(k, h, \varepsilon) = \varepsilon^{1-\eta_k} k^{\eta_k} h^{\eta_h} \), where \( \eta_k > 0, \eta_h > 0 \) and \( \eta_k + \eta_h < 1 \), so we still have DRS. In this case CM profit is

\[
\Pi(k, \varepsilon) = \max_h \varepsilon^{1-\eta_k} k^{\eta_k} h^{\eta_h} - wh.
\]

Letting \( B(w) \equiv (\frac{\varepsilon}{w})^{1-\eta_h} \), the solution is \( h = \varepsilon B(w) k^n \), which means \( \Pi(k, \varepsilon) = B(w) \varepsilon k^n \) takes over the role of \( f(k) \) in Section 5.

Given \( w \) the previous approach yields two equations in \((k, q)\)

\[
\begin{align*}
l &= \xi \Lambda(k, q), \quad (34) \\
r + \delta &\quad \frac{1}{1 - \tau} = B(w) H(k, q), \quad (35)
\end{align*}
\]

where

\[
H(k, q) = \gamma_H \varepsilon_H \eta [\alpha \gamma_L (k + q)^{\eta - 1} \Omega(k, q) + (1 - \alpha \gamma_L) k^{\eta - 1}] \\
+ \gamma_L \varepsilon_L \eta [\alpha \gamma_H (k - q)^{\eta - 1} \Gamma(k, q) + (1 - \alpha \gamma_H) k^{\eta - 1}],
\]

and \( \Lambda, \Omega \) and \( \Gamma \) are similar to Section 5. To determine \( w \), use the market clearing condition

\[
\delta k + c + g = Y(w, k), \quad (36)
\]

where \( u'(c) = A/w \) and \( Y(w, k) \) is output given \( w \) and \( k \),

\[
Y(w, k) = \frac{B(w)}{1 - \eta_h} \gamma_H \varepsilon_H [\alpha \gamma_L (k + q)^{\eta} + (1 - \alpha \gamma_L) k^{\eta}] \\
+ \frac{B(w)}{1 - \eta_h} \gamma_L \varepsilon_L [\alpha \gamma_H (k - q)^{\eta} + (1 - \alpha \gamma_H) k^{\eta}].
\]

The system reduces to two equations in \((k, q)\) as in Section 5, because we can solve \( w \) as a function of \((k, q)\) using (35). Using this and \( u'(c) = A/w \) to eliminate \( c \) and \( w \) from (36), we obtain
\[
Y \left( \eta_h \left[ \frac{(1 - \eta_h)(1 - \tau) H(k, q)}{r + \delta} \right]^{-\frac{1 - \eta_h}{\eta_h}}, k \right) \\
= \delta k + u' \left( \frac{A}{\eta_h} \left[ \frac{(1 - \eta_h)(1 - \tau) H(k, q)}{r + \delta} \right]^{-\frac{1 - \eta_h}{\eta_h}} \right) + g.
\]

Now \((k, q)\) is determined by \((34)-(37)\), the LM and IS curves for this version. At \(q = 0\), \((37)\) reduces to
\[
\frac{A}{\eta_h} \left[ \frac{(1 - \eta_h)(1 - \tau) H(k, 0)}{r + \delta} \right]^{-\frac{1 - \eta_h}{\eta_h}} = u' \left\{ \left[ \frac{r + \delta}{(1 - \tau)(1 - \eta_h)} - \delta \right] k - g \right\}.
\]

The LHS is increasing in \(k\) and the RHS is decreasing in \(k\). Also, if \(k\) small, the RHS large, so there exists a unique \(k_0 > 0\) solving this condition. Similarly, one can show that there exists a unique \(\bar{k}\) solving \((37)\). This suggests IS starts at \((k, 0)\) in \((k, q)\) space and reaches the 45\(^o\) line at \((\bar{k}, \bar{k})\). If \(\iota\) is not too big, the LM curve starts at \((0, 0)\) and goes to \((\infty, \infty)\). By continuity, these two curves have to intersect at least once. While this version is complicated because \(c\) and \(w\) are endogenous, the economics is similar.

### 6.3 Competitive Search

Instead of random search and bargaining, consider directed search and price posting, a combination called competitive search equilibrium (see the survey by Wright et al. 2018). This means agents can communicate before they meet in the DM by posting the terms of trade, to which they commit, as a way to compete for counterparties. As is well known from other applications, this kind of communication and commitment can enhance efficiency relative to bargaining after agents meet. Heuristically, competitive search can be understood as overcoming holdup problems like those in the benchmark model, which allows us to isolate the effects coming from other features of the formulation.

Note that being able to commitment to the DM prices does not mean agents can commit to everything; so we can either use or not use the frictions discussed
above that preclude perfect credit. Also, since we get the same outcome whether sellers post and buyers choose where to search, or vice versa, for convenience we let buyers post.\footnote{While it is often equivalent to have buyers post and sellers search or vice versa, there are exceptions (Delacroix and Shi 2017). There is a third approach, where third parties called market makers set up submarkets posting terms to attract both buyers and sellers, that also delivers the same outcome, at least if we get around the complications in Faig and Huangfu (2007) by, say, the method in Rocheteau and Wright (2005).} Then the set of buyers posting the same terms, plus the set of sellers directing their search toward them, defines a submarket. Although sellers direct their search to a particular submarket, within submarkets there are still bilateral random meetings, where $\alpha_s = \alpha(n)$ is the probability a seller meets a buyer, $\alpha_b = \alpha(n)/n$ is the probability a buyer meets a seller, $n = n_b/n_s$ is submarket tightness, and $\alpha(n)$ satisfies the usual assumptions.

As in Section 5, consider $F(k, h, \varepsilon) = \varepsilon f(k) + h$ and a two-point $\varepsilon$ distribution. Then buyers are firms realizing $\varepsilon_H$, after which they post DM terms. When they post, therefore, $z$ and $k$ are predetermined from the CM. Also, anticipating some results, in equilibrium all active submarkets are the same and hence all have $n = \gamma_H/\gamma_L$, but to find equilibrium we first let $n$ be a choice and then equilibrate $n = \gamma_H/\gamma_L$. What gets posted is $(p, q, n)$, meaning this: when buyers and sellers meet in this submarket, they trade $q$ units of capital for a payment $p$, and tightness in this submarket is $n$ (as usual, it is not important to post $n$, as agents can figure it out from $p$ and $q$).

The buyer’s posting problem is then

\[
v_b = \max_{p,q,n} \frac{\alpha(n)}{n} A \{ (1 - \tau) \varepsilon_H \left[ f(k_b + q) - f(k_b) \right] - p \} \tag{38}
\]

\[
\text{st} \quad \alpha(n) A \{ p - \varepsilon_L (1 - \tau) \left[ f(k_s) - f(k_s - q) \right]\} = v_s,
\]

where lower case $v_j$ is the per-period version of $V_j$. The constraint says buyers can get sellers iff they match their market payoff $v_s$, which is taken as given by individuals but is endogenous in equilibrium. There is another constraint $p \leq z$, since buyers cannot hand over cash they do not have, but without loss of generality we can set $z = p$. From (38) we get the terms of trade as functions of
(z, ks). Then solving the CM problem for (z, ks) we obtain

\[ \iota = \frac{\alpha(n) \gamma_H \varepsilon_H f'(k + q) - \varepsilon_L f'(k - q)}{\varepsilon_L f'(k - q)} \]  

\[ \frac{r + \delta}{1 - \tau} = \psi f'(k) + \xi \varepsilon_H f'(k + q) + \xi \varepsilon_L f'(k - q). \]  

This system is shown by the IS and LM curves in Figure 7. Then we have:

**Proposition 9** For the convenient parameterization with competitive search, monetary steady state exists iff \( \iota < \hat{\iota} \equiv \alpha_H \gamma_H (\varepsilon_H - \varepsilon_L) / \varepsilon_L \). When it exists it is unique. If \( \tau = 0 \) perfect-credit equilibrium is efficient and monetary equilibrium is efficient iff \( \iota = 0 \).

Similar to Proposition 5 existence requires \( \iota \) below a threshold, but now the threshold is bigger; intuitively, this is because competitive search is a better trading arrangement. Also, although IS is nonmonotone, we get uniqueness even without the parameter conditions Proposition 5 (heuristically, one might say that competitive search delivers uniqueness because posting internalizes complements in the choices of \( k \) and \( z \), as discussed in Rocheteau and Wright 2005). The efficiency results follow immediately from comparing the planner’s problem to equilibrium with perfect credit and to equilibrium with money. In terms of policy, higher \( \tau \) decreases both \( k \) and \( q \); while higher \( \iota \) decreases \( q \) but can in general increase or decrease \( k \), depending on whether the LM curve intersects the IS curve in its increasing or decreasing region.

**FIGURE 7 ABOUT HERE**

If instead of \( F(k, h, \varepsilon) = \varepsilon f(k) + h \) we use the slightly less convenient version \( F(k, h, \varepsilon) = \varepsilon^{1-\eta} k^{\eta_h} h^{\eta} \), as in Section 6.2, the outcome is characterized by

\[ \iota = \frac{\alpha(n) \gamma_H \varepsilon_H (k + q)^{\eta - 1} - \varepsilon_L (k - q)^{\eta - 1}}{\varepsilon_L (k - q)^{\eta - 1}} \]

\[ \frac{r + \delta}{(1 - \tau) \eta B(w)} = \psi k^{\eta - 1} + \xi \varepsilon_H (k + q)^{\eta - 1} + \xi \varepsilon_L (k - q)^{\eta - 1}. \]
plus the market clearing condition (36). One can use the methods discussed above to reduce this to two equations in \((k, q)\) and study existence, uniqueness, and the effects of policy. We do not pursue that further, for now, but emphasize that competitive search is quite tractable in these setups.\(^{17}\)

7 Quantitative Analysis

We now analyze the quantitative implications of the model using the Cobb-Douglas technology in Section 6.2 and a CM utility function \(u(c) = \log(c)\). Also we restrict attention to the case where \(\varepsilon\) has a two-point distribution. Moreover, we assume here that only half of the firms can access the used capital market in any given period — an additional friction that helps match some observations — and introduce a labor tax \(\tau_h\), so the capital tax is now denoted \(\tau_k\). Then a quarterly model is calibrated to the US economy from 1984 onwards.\(^{18}\)

Table 1 shows the targets and calibrated parameter values. Many of these are standard, so we focus on others. Low-productivity firms are assumed 60% as productive as high-productivity firms, and with mean normalized to 1 we end up with \(\varepsilon_H = 1.25\) and \(\varepsilon_L = 0.75\). The credit limit \(D\) is set to match a 20% down payment ratio and the meeting probability \(\alpha\) is set to match the spending on used capital as a fraction of total investment spending. There is little data on the bargaining power \(\theta\), so as a benchmark we set it to 0.5, motivated by the fact that buyers and sellers are symmetric, and then consider robustness on this dimension.

\(^{17}\)Again, directed search and posting is a relatively good way to organize markets, compared to random search and bargaining, but it does require communication and commitment. Actual capital markets are probably in between, with some trade better characterized by random search and bargaining, and other trade by directed search and posting. In principle, we could combine them in one model (see Lester 2011 or Bethune et al. 2018 for examples in goods markets), with shares disciplined by the data, but that is beyond the scope of this project.

\(^{18}\)We choose this period because the ratio of expenditure on used capital to total investment has a trend prior to 1984 (Cui 2017). The other series are chosen to be consistent with this. The annual real interest rate is obtained by subtracting inflation from the Aaa bond yield, both from the FRED database. The benchmark calibration does not exclude the period of the financial crisis, but results are robust to that detail. We also tried a monthly calibration and found similar results.

Table 1: Parameters for Quantitative Analysis

7.1 Monetary Policy

Figure 8 shows how $\iota$ changes the economy across steady states at the calibrated parameters, where $\iota$ is the annualized nominal interest rate. Except for the L/E ratio, i.e., capital liquidation (or resale) divided by the total investment expenditure, all variables are normalized such that they take the value 1 at $\iota = 0$, the Friedman rule. The total capital stock, output and total employment are non-monotone in $\iota$, decreasing for small $\iota$ and increasing for large $\iota$. At the current nominal interest $\iota = 6.72\%$, higher $\iota$ decreases the capital stock, employment and output, consistent with Keynesian thinking, although for different reasons, as we said above. The real price of used capital is increasing in $\iota$ for most values of $\iota$, a consequence of two forces: higher $\iota$ decreases $q$ and $k$ for the most $\iota$; and both effects raises the value of an additional unit of capital to firms. Reallocation shuts down if $\iota$ is around 11%, which corresponds to an inflation rate around 7%.19

19If we embed households’ demand for money into the model, as described in Section 6.1, they may still hold cash for their DM transactions even if $\iota$ is above 11%; hence we are not too worried that monetary exchange breaks down where $\iota$ is above 11% in this version. Indeed,
We also plot the standard deviation of the cross-sectional distribution of the 
 marginal product of capital (MPK), which is sometimes considered a measure 
of misallocation. Although it may be difficult to discern from the graph, this 
standard deviation is non-monotone in $\iota$, first decreasing and then increasing with $\iota$. Note that $\iota$ can be interpreted as a financial friction, because higher $\iota$ reduces liquidity, and that has an effect similar to a lower borrowing limit. Therefore, 
our result suggests that a lower standard deviation of MPK does not necessarily 
imply reduced frictions. Moreover, it does not necessarily imply higher output 
because here, if $\iota$ is around 10%, increasing it raises both output and the standard 
deviation of MPK. This is due to the general equilibrium impact of $\iota$ on $k$. If $\iota$ 
increases, it is harder to trade in the used capital market, so investment in the 
primary market goes up, increasing the capital stock and output.

For under different values of $\theta$, Figure 9 shows the impact of monetary policy 
on welfare measured in the usual way – the percentage of consumption that a 
household is willing to give up to go to $\iota = 0$ from some $\iota > 0$. Notice that at 
$\theta = 0.5$ implies the welfare cost of inflation is increasing in $\iota$. Hence, the standard 
deviation of MPK is not monotone in welfare. Moreover, the welfare cost is very 
large: 10% annual inflation can reduce welfare by around 6.0%. This is similar 
to the numbers in Lagos and Wright (2005) in a setting where inflation taxes 
household consumption, although more recently, using other models and methods, 
those numbers have been revised downward (e.g., see Bethune et al. 2018). Here 
$\iota$ affects the accumulation of capital through the secondary market, which can 
have a big welfare effect. As $\theta$ increases, the welfare cost of inflation decreases, 
but even at $\theta = 1$, which yields the lowest welfare cost, a 10% annual inflation 
leads to a 3% welfare loss.

\footnotesize{in a version with households and firms both demanding money, if $\iota$ fluctuates over time the 
latter might use cash in some periods but not others. Also, in a version where firms were 
heterogeneous with respect to more than just current $\varepsilon$, some of them will use cash at higher $\iota$ 
while others only use it at lower $\iota$. In any event, for the record, if $\theta$ increases to 0.8 monetary 
equilibrium does not fail to exist in this benchmark model until $\iota$ reaches 15%.}
The implication of these findings is that inflation can be very important for welfare when it affects firms' liquidity in environments with frictional capital reallocation. Since it is well known that some of the impact of inflation depends on bargaining, for comparison we also calibrate a version of the model with competitive search. Results are shown in Figure 10. Compared to the bargaining model, the monetary equilibrium exists until $\tau$ reaches about 19%, and again output, hours and capital are non-monotone in $\tau$. Under competitive search, welfare is decreasing in inflation, and a 10% inflation reduces welfare by around 3.2%. So even without bargaining frictions inflation can be very important for welfare in this kind of environment.

7.2 Stylized Facts

Now we show how the model can match some stylized facts deemed interesting in the literature: capital reallocation is procyclical; capital mismatch is countercyclical; the price of capital in the secondary market is procyclical; and spending on capital in this market, as a fraction of total investment, is procyclical. We consider two exogenous changes that could drive the cycle: increasing productivity; and expanding credit conditions as measured by increasing $\chi$. As it turns out, we need both to match the facts.

First, consider only a productivity shock. To generate a boom, we increase $\varepsilon_L$ but keep $\varepsilon_H$ fixed, appealing to the findings in Kehrig (2015) that dispersion in productivity is countercyclical, with firms at the lower end more affected by business cycles. The results are shown in Figure 11. The model is consistent

\[\text{As Kehrig (2015) says: “First, cross-sectional productivity dispersion is countercyclical; the distribution of total factor productivity levels across establishments is about 12% more spread-out in a recession than in a boom. Second, the bottom quantiles of the productivity distribution are more cyclical than the top quantiles. In other words, the countercyclicality of productivity dispersion is mostly due to a higher share of relatively unproductive establishments during downturns.” While we do not calibrate to match these numbers, we use the general idea.}\]
with many stylized facts except that spending on the used capital is counterfactual, i.e. the L/E ratio decreases as output increases. Intuitively, higher $\varepsilon_L$ leads to less capital reallocation because low productivity firms are less willing to sell capital. This is true as long as $\varepsilon_H$ does not increase as much as $\varepsilon_C$. Alternatively, suppose only credit conditions improve, as shown in Figure 12. This makes the price of used capital counterfactual, i.e. it decreases with output. Now buyers can buy more in a boom because credit conditions are better, and due to DRS buyers are willing to pay less for additional capital, so the average unit price drops.

**FIGURES 11 and 12 ABOUT HERE**

Figure 13 shows what happens if both productivity and credit conditions improve. This can generate all the stylized facts. Improved credit conditions increase in reallocation in a boom, but the negative effect on the price of used capital is off-set by increased $\varepsilon_L$, and the net effects together generate all the stylized facts. This is consistent with Eisfeldt and Shi (2018), who also show that a productivity shock is not able to generate increasing reallocation but expansion in credit conditions can.\textsuperscript{21} We also mention that only expansion in credit conditions is not likely to increases the price of used capital if only the traded capital can be used as collateral. However, credit conditions can increase the price if the bargaining power of the seller is close to 0.

**FIGURE 13 ABOUT HERE**

### 8 Conclusion

This paper explored the determination of capital investment and reallocation in dynamic general equilibrium. The theory included frictional secondary markets

\textsuperscript{21}As they put it, “aggregate productivity shocks alone are unlikely to generate a realistic business cycle correlation for capital reallocation; higher aggregate productivity alone does not lead to greater capital reallocation in either a frictionless model, or a model with financial or real trading frictions. In contrast, relaxing financial constraints increases reallocation.”
with credit and monetary exchange, as well as different microstructures, including random search and bargaining plus directed search and posting. For each specification we provided results on existence, uniqueness, efficiency and policy. The framework is tractable: it can be reduced to two equations for capital and money – or, if one prefers, for investment and reallocation. Depending on parameters, decreasing the nominal interest rate can stimulate real investment and output, consistent with Keynesian macroeconomics, even if our approach to microfoundations is very different. In some versions of the model, inflation above the Friedman rule is optimal because, while it hinders the secondary market, it encourages investment in the primary market.

We also argued that common measures of mismatch related to productivity dispersion do not necessarily capture frictions. Furthermore, we showed how the model can account for some stylized facts, at least if there are changes in both productivity and credit conditions. All of this helps us better understand issues related to investment and reallocation, and to the effects of monetary and fiscal policy. In terms of future research, one could further pursue the quantitative analysis after relaxing a few special assumptions, like i.i.d. shocks or having only two realizations of the shocks. One could also add aggregate shocks. It also might be interesting to examine endogenous growth, to allow liquid assets other than currency to facilitate trade, to introduce explicitly financial intermediation, to combine frictional capital and frictional labor markets, or to incorporate other extensions that have proved useful elsewhere in related models. All of this is left for future work.
Appendix

Proof of Proposition 4: We want to show IS and CR cross uniquely in \((k, q)\) space at \(k > 0\) and \(q > 0\). First, let \(\Delta = (\partial q/\partial K)_{IS} - (\partial q/\partial K)_{CR}\) and derive

\[
\Delta = \frac{\varepsilon_H f''(k + q) + \varepsilon_L f''(k - q) + \psi f''(k)}{\Phi(k, q)} - \frac{\Phi(k, q)}{\varepsilon_H f''(k + q) + \varepsilon_L f''(k - q)}.
\]

Consider case (i): \(\Phi(k, q) < 0\) when the curves cross. Letting \(\approx\) indicate both sides take the same sign, we have

\[
\Delta \approx \left[\varepsilon_H f''(k + q) + \varepsilon_L f''(k - q)\right]^2 + \left[\varepsilon_H f''(k + q) + \varepsilon_L f''(k - q)\right] \psi f''(k) / \xi - \Phi(k, q)^2.
\]

As the RHS can be shown to be positive, IS is steeper than CR when they cross.

Consider next case (ii): \(\Phi(k, q) > 0\) when the curves cross. Then

\[
\Delta \approx -\left[\varepsilon_H f''(k + q) + \varepsilon_L f''(k - q)\right]^2 + \left[\varepsilon_H f''(k + q) + \varepsilon_L f''(k - q)\right] \psi f''(k) / \xi + \Phi(k, q)^2 - \Phi(k, q)^2.
\]

As the RHS can be shown to be negative, IS is again steeper than CR when they cross.

Hence, in either case, given IS and CR are single-valued functions, they cannot cross more than once. To show they cross, notice CR satisfies \(Q(0) = 0\) and \(0 < Q(k) \leq k \ orall k > 0\). Also, as \(k \to \infty\), \(k - Q(k) \to \infty\), because \(\varepsilon_H f'[k + Q(k)] > \varepsilon_H f'(k) \to 0\), implying \(\varepsilon_L f'[k - Q(k)] \to 0\). Similarly, the IS curve satisfies \(K(0) > 0\) and \(K(q) - q \to c < \infty\) as \(q \to \infty\). Now having the curves cross is equivalent to finding a solution to

\[
Q \circ K(q) - q = 0,
\]

where \(\circ\) denotes the composite of functions. Notice \(Q \circ K(0) > 0\), and as \(q \to \infty\)

\[
Q \circ K(q) - q = Q \circ K(q) - K(q) + K(q) - q \to c - \infty = -\infty.
\]
Hence there exists $q^* > 0$ solving (41), and the curves cross at $q^*$ and $K (q^*)$. ■

**Proof of Proposition 5:** As long as $\iota$ is not too big, (28) defines $q$ as a function of $k$, say $q = Q (k)$ where

\[
Q (k) = \frac{f' (k + q) f'' (k - q) - f' (k - q) f'' (k + q)}{f' (k + q) f'' (k - q) + f' (k - q) f'' (k + q)} \approx \frac{\partial}{\partial q} [f' (k + q) f' (k - q)].
\]

Notice $Q (0) = 0$, $Q (k) > 0$ if $k > 0$, and $Q' (k) < 1$. Similarly, (29) defines $k$ as a function of $q$, say $k = K (q)$. Let $k_0$ satisfy $r + \delta = (1 - \tau) (\gamma_H \varepsilon_H + \gamma_L \varepsilon_L) f' (k_0)$. Then $K (0) = k_0$. In addition, let $\bar{k}$ satisfy

\[
\frac{r + \delta}{1 - \tau} = \gamma_H \alpha_H \theta \varepsilon_H f' (2\bar{k}) + \gamma_H \varepsilon_H (1 - \alpha_H) f' (\bar{k}) + \gamma_L \alpha_L (1 - \theta) \varepsilon_H f' (2\bar{k}) + \gamma_L \varepsilon_L f' (\bar{k}).
\]

Then $\bar{k} = K (\bar{k})$. Any $q$ solves $Q \circ K (q) = q$ is an equilibrium. Notice $Q \circ K (0) = Q (k_0) > 0$ and $Q \circ K (\bar{k}) = Q (\bar{k}) < \bar{k}$. Then, by continuity, there exists at least one equilibrium.

If $\theta = 1$, one can check the FOC’s are sufficient. Therefore, $(k, q)$ is a steady state equilibrium iff it satisfies

\[
\iota = \alpha_H \gamma_H \left[ \frac{\varepsilon_H f' (k + q)}{\varepsilon_L f' (k - q)} - 1 \right] \quad (42)
\]

\[
r + \delta = \gamma_H \alpha_H \varepsilon_H f' (k + q) + (1 - \alpha_H) \gamma_H \varepsilon_H f' (k) + \gamma_L \varepsilon_L f' (k). \quad (43)
\]

Uniqueness follows if $K' (q) Q' \circ K (q) < 0$ whenever $Q \circ K (q) = 0$. To check this, notice

\[
K_2' (q) Q_1' \circ K_2 (q) = f' (k + q) f'' (k - q) \gamma_H \alpha_H \varepsilon_H f'' (k + q)
- \gamma_H \alpha_H \varepsilon_H f'' (k + q) f' (k - q) f'' (k + q)
- [f' (k + q) f'' (k - q) + f' (k - q) f'' (k + q)]
\times [(1 - \alpha_H) \gamma_H \varepsilon_H f'' (k) + \gamma_L \varepsilon_L f' (k)] < 0.
\]

This proves uniqueness.
Now we have

\[ \begin{align*}
\nu &= \alpha_H \gamma_H \theta [\varepsilon_H f'(k + q) - \varepsilon_L f'(k - q)] / D \\
\frac{r + \delta}{1 - \tau} &= \gamma_H \varepsilon_H [\alpha \gamma_L f'(k + q) + (1 - \alpha \gamma_L) f'(k)] \\
&\quad + \gamma_L \varepsilon_L [\alpha \gamma_H f'(k - q) + (1 - \alpha \gamma_H) f'(k)].
\end{align*} \]

(44)

(45)

\[ \Omega(k, q) = [(1 - \theta) \varepsilon_H f'(k) + \theta \varepsilon_L f'(k - q)] / D \]

\[ \Gamma(k, q) = [(1 - \theta) \varepsilon_H f'(k + q) + \theta \varepsilon_L f'(k)] / D \]

If \( \theta > 0 \) and \( \nu = 0 \), (28) and (29) reduces to

\[ \frac{\dot{\gamma}}{1 - \tau} = \varepsilon_H f'(k + q) - \varepsilon_L f'(k - q) \]

\[ \frac{r + \delta}{1 - \tau} = \gamma_H \{\alpha \gamma_L [(1 - \theta) \varepsilon_H f'(k) + \theta \varepsilon_L f'(k - q)] + (1 - \alpha \gamma_L) \varepsilon_H f'(k)} \]

\[ + \gamma_L \{\alpha \gamma_H [(1 - \theta) \varepsilon_H f'(k + q) + \theta \varepsilon_L f'(k)] + (1 - \alpha \gamma_H) \varepsilon_L f'(k)} \].

\[ \frac{\dot{J}}{11} = \varepsilon_H f'(k + q) + \varepsilon_L f''(k - q) \]

\[ \frac{\dot{J}}{12} = \varepsilon_H f''(k + q) - \varepsilon_L f''(k - q) \]

\[ \frac{\dot{J}}{21} = \alpha \gamma_L \gamma_H \{[(1 - \theta) \varepsilon_H f''(k) + f''(k + q)] - \theta \varepsilon_L [f''(k - q) - f''(k)]} \]

\[ + \varepsilon_H \gamma_H (1 - \alpha \gamma_L) f''(k) + \varepsilon_L \gamma_L (1 - \alpha \gamma_H) f''(k). \]

\[ \frac{\dot{J}}{22} = \alpha \gamma_L \gamma_H \{[(1 - \theta) \varepsilon_H f''(k) + f''(k + q)] + \theta \varepsilon_L [f''(k - q) + f''(k)]} \]

Obviously, \( \dot{J}_{11} < 0 \) and \( \dot{J}_{22} < 0 \). One can show that, at the equilibrium \( k \) and \( q \),

\[ K'_2(q) Q'_1 \circ K_2(q) - 1 = \frac{\dot{J}_{12} \dot{J}_{21}}{\dot{J}_{11} \dot{J}_{22}} - 1 \approx \dot{J}_{12} \dot{J}_{21} - \dot{J}_{11} \dot{J}_{22} < 0 \]

which implies uniqueness for \( \nu = 0 \). By continuity this also holds for \( \nu \) not too big. \( \blacksquare \)

**Proof of Proposition 7:** One can show that welfare is determined by

\[ W = - (r + \delta) k + \gamma_H \varepsilon_H \alpha_H f(k + q) + \gamma_H \varepsilon_H [1 - \alpha_H] f(k) \]

\[ + \gamma_L \varepsilon_L \alpha_L f(k - q) + \gamma_L \varepsilon_L [1 - \alpha_L] f(k), \]

36
which is the total benefit of capital minus the cost. To show the optimal $\iota^*$ is positive for some $\theta$, we only need check $(\partial W / \partial t)|_{t=0} > 0$. Notice that

$$\frac{\partial W}{\partial t}|_{t=0} = N_k \frac{\partial k}{\partial t}|_{t=0}$$

where $N_k$ is the net marginal benefit of capital:

$$N_k = -(r + \delta) + \gamma_H \varepsilon_H \alpha_H f'(k + q) + \gamma_H \varepsilon_H (1 - \alpha_H) f'(k) + \gamma_L \varepsilon_L \alpha_L f'(k - q) + \gamma_L \varepsilon_L (1 - \alpha_L) f'(k).$$

Notice $NB_k = 0$ if $\theta = \theta^*$. Now $\theta > \theta^*$ implies $k < k^*$ and $NB_k > 0$ and $\theta < \theta^*$ implies $k > k^*$. Therefore, $\theta < \theta^*$ implies $(\partial W / \partial t)|_{t=0} > 0$ iff $(\partial k / \partial t)|_{t=0} < 0$, and $\theta > \theta^*$ implies $(\partial W / \partial t)|_{t=0} > 0$ iff $(\partial k / \partial t)|_{t=0} > 0$.

Next, totally differentiate (28)-(29) and evaluate the result at the equilibrium $(k, q)$ with $\iota = 0$. It turns out to be easier to rewrite (29) using $\iota = \gamma_H \alpha_H \Lambda (k, q)$ and obtain

$$r + \delta = \alpha \gamma_H \gamma_L \theta \varepsilon_H f'(k + q) - \iota (1 - \theta) \varepsilon_H [f'(k + q) - f'(k)]$$

$$+ \alpha \gamma_L \gamma_H (1 - \theta) \varepsilon_L f'(k - q) - \iota (1 - \theta) \varepsilon_L [f'(k) - f'(k - q)]$$

$$+ \psi f'(k).$$

Then use (28) and (46) and the fact that $\varepsilon_H f'(k + q) = \varepsilon_L f'(k - q)$ to obtain, at $\iota = 0$,

$$[Y_0 \ Y_0 \ Y_1 \ Y_2] \left[ \begin{array}{c} \partial q \\ \partial k \end{array} \right] = \left[ \begin{array}{c} 1 \\ -(1 - \theta) (\varepsilon_H - \varepsilon_L) f'(k) \end{array} \right] \partial t$$

where

$$Y_0 = \alpha \gamma_H \gamma_L \theta [\varepsilon_H f''(k + q) + \varepsilon_L f''(k - q)] / D$$

$$Y_1 = \alpha \gamma_H \gamma_L [\theta \varepsilon_H f''(k + q) - (1 - \theta) \varepsilon_L f''(k - q)],$$

$$Y_2 = \alpha \gamma_H \gamma_L \theta \varepsilon_H f''(k + q) + \alpha \gamma_L \gamma_H (1 - \theta) \varepsilon_L f''(k - q)$$

$$+ \psi f''(k).$$

The determinant of the Jacobian matrix is equal in sign to

$$\alpha \gamma_H \gamma_L [\varepsilon_H f''(k + q) + \varepsilon_L f''(k - q)] [\theta \varepsilon_H f''(k + q) + (1 - \theta) \varepsilon_L f''(k - q)]$$

$$- \alpha \gamma_H \gamma_L \Phi (k, q) [\theta \varepsilon_H f''(k + q) - (1 - \theta) \varepsilon_L f''(k - q)]$$

$$+ \alpha \gamma_H \gamma_L \psi [\varepsilon_H f''(k + q) + \varepsilon_L f''(k - q)] f''(k).$$
One can check that the above expression is positive, so by Cramer’s rule,

\[
\frac{\partial k}{\partial \iota}|_{\iota=0} \approx -\theta (1 - \theta) \left[ \varepsilon_H f''(k + q) + \varepsilon_L f''(k - q) \right] (\varepsilon_H - \varepsilon_L) f'(k) - [\theta \varepsilon_H f''(k + q) - (1 - \theta) \varepsilon_L f''(k - q)] \varepsilon_H f'(k + q).
\]

The first term is positive and the second can be positive or negative depending on \(\theta\). If \(\theta = 1\), the first term is 0 while the last term is positive. By continuity, there exists \(\theta_H > \theta^*\) such that \((\partial k/\partial \iota)|_{\iota=0} > 0\) \(\forall \theta > \theta_H\) and hence \((\partial W/\partial \iota)|_{\iota=0} > 0\).

Similarly, if \(\theta = 0\) then \((\partial k/\partial \iota)|_{\iota=0} < 0\), and by continuity, \(\theta < \theta_L \leq \theta^*\) implies \((\partial k/\partial \iota)|_{\iota=0} < 0\) and \((\partial W/\partial \iota)|_{\iota=0} > 0\). In either case, \(\iota > 0\) yields higher welfare than \(\iota = 0\), but does not achieve the first best because \(q\) is not efficient.

Now suppose that \(f(k) = k^{\eta}\). At \(\iota = 0\), one can show that \(q = ck\) where

\[
c = \frac{(\varepsilon_H/\varepsilon_L)^{1/\eta} - 1}{(\varepsilon_H/\varepsilon_L)^{1/\eta} + 1} = \frac{\varepsilon_H^{1/\eta} - \varepsilon_L^{1/\eta}}{\varepsilon_H^{1/\eta} + \varepsilon_L^{1/\eta}}.
\]

From this we obtain

\[
\frac{\partial k}{\partial \iota}|_{\iota=0} \approx \theta (1 - \theta) \left[ \varepsilon_H (1 + c)^{\eta-2} + \varepsilon_L (1 - c)^{\eta-2} \right] (\varepsilon_H - \varepsilon_L) + \left[ \theta \varepsilon_H (1 + c)^{\eta-2} - (1 - \theta) \varepsilon_L (1 - c)^{\eta-2} \right] \varepsilon_H (1 + c)^{\eta-1}.
\]

The RHS is a quadratic function of \(\theta\) with roots

\[
\theta_1 = \frac{1 + \frac{\varepsilon_H (1 + c)^{\eta-1}}{\varepsilon_H - \varepsilon_L} + \sqrt{\left[1 + \frac{\varepsilon_H (1 + c)^{\eta-1}}{\varepsilon_H - \varepsilon_L}\right]^2 - 4 \frac{\varepsilon_H \varepsilon_L (1 - c)^{\eta-2} (1 + c)^{\eta-1}}{\varepsilon_H (1 + c)^{\eta-2} + \varepsilon_L (1 - c)^{\eta-2}}}}{2},
\]

\[
\theta_2 = \frac{1 + \frac{\varepsilon_H (1 + c)^{\eta-1}}{\varepsilon_H - \varepsilon_L} - \sqrt{\left[1 + \frac{\varepsilon_H (1 + c)^{\eta-1}}{\varepsilon_H - \varepsilon_L}\right]^2 - 4 \frac{\varepsilon_H \varepsilon_L (1 - c)^{\eta-2} (1 + c)^{\eta-1}}{\varepsilon_H (1 + c)^{\eta-2} + \varepsilon_L (1 - c)^{\eta-2}}}}{2}.
\]

Notice that \(\theta_1 > 1\) and \(\theta_2 \in (0, 1)\) if

\[
\frac{\varepsilon_H \varepsilon_L (1 - c)^{\eta-2} (1 + c)^{\eta-1}}{[\varepsilon_H (1 + c)^{\eta-2} + \varepsilon_L (1 - c)^{\eta-2}]} (\varepsilon_H - \varepsilon_L) < \frac{\varepsilon_H (1 + c)^{\eta-1}}{\varepsilon_H - \varepsilon_L}.
\]

This condition is equivalent to

\[
\frac{\varepsilon_L (1 - c)^{\eta-2}}{\varepsilon_H (1 + c)^{\eta-2} + \varepsilon_L (1 - c)^{\eta-2}} < 1,
\]

38
which always holds. Therefore, \((\partial k/\partial \theta)|_{\epsilon=0} > 0\) if \(\theta \in (\theta_2, 1]\) and \((\partial k/\partial \theta)|_{\epsilon=0} < 0\) if \(\theta \in [0, \theta_2)\).

We now show that \(\theta_2 > \theta^*\). Notice

\[
\theta^* = \frac{\varepsilon_H - B^{1-\eta}}{\varepsilon_H - \varepsilon_L},
\]

\[
\theta_2 = \frac{\varepsilon_H - \varepsilon_L + B^{1-\eta} - \sqrt{[\varepsilon_H - \varepsilon_L + B^{1-\eta}]^2 - 2B^{1-\eta}\varepsilon_H^{\frac{1-\eta}{B}}(\varepsilon_H - \varepsilon_L)} - \frac{2B^{1-\eta}\varepsilon_H^{\frac{1-\eta}{B}}(\varepsilon_H - \varepsilon_L)}{2(\varepsilon_H - \varepsilon_L)}.
\]

where \(B\) is defined in the statement of this Proposition. Therefore,

\[
\theta_2 - \theta^* \approx 3B^{1-\eta} - (\varepsilon_H + \varepsilon_L) - \sqrt{B^{2(1-\eta)} + (\varepsilon_H - \varepsilon_L)\left[2B^{1-\eta} + \varepsilon_H - \varepsilon_L - 2\frac{B^{1-\eta}\varepsilon_H^{\frac{1-\eta}{B}}}{B}\right]}.
\]

This is positive if

\[
3B^{1-\eta} - (\varepsilon_H + \varepsilon_L) > \sqrt{B^{2(1-\eta)} + (\varepsilon_H - \varepsilon_L)\left[2B^{1-\eta} + \varepsilon_H - \varepsilon_L - 2\frac{B^{1-\eta}\varepsilon_H^{\frac{1-\eta}{B}}}{B}\right]}.
\]

After some algebra, one can show the previous inequality is equivalent to

\[
[2B^{1-\eta} - (\varepsilon_H + \varepsilon_L)] \left[4B^{1-\eta} - (\varepsilon_H + \varepsilon_L)\right] > -B^{1-\eta}\varepsilon_H^{\frac{1-\eta}{B}} - \varepsilon_L^{\frac{1-\eta}{B}}(\varepsilon_H - \varepsilon_L) + (\varepsilon_H - \varepsilon_L)^2.
\]

By Hölder’s inequality, \(B^{1-\eta} \geq (\varepsilon_H + \varepsilon_L)/2\). This means that the LHS is positive. For the RHS, notice

\[
-B^{1-\eta}\varepsilon_H^{\frac{1-\eta}{B}} - \varepsilon_L^{\frac{1-\eta}{B}}(\varepsilon_H - \varepsilon_L) + (\varepsilon_H - \varepsilon_L)^2
\]

\[
\approx -B^{1-\eta}\left(\varepsilon_H^{\frac{1-\eta}{B}} - \varepsilon_L^{\frac{1-\eta}{B}}\right) + (\varepsilon_H - \varepsilon_L)B
\]

\[
\leq -\frac{(\varepsilon_H + \varepsilon_L)}{2}\left(\varepsilon_H^{\frac{1-\eta}{B}} - \varepsilon_L^{\frac{1-\eta}{B}}\right) + (\varepsilon_H - \varepsilon_L)\left(\frac{\varepsilon_H^{\frac{1-\eta}{B}}}{2} + \frac{\varepsilon_L^{\frac{1-\eta}{B}}}{2}\right)
\]

\[
\approx -(\varepsilon_H + \varepsilon_L)\left(\varepsilon_H^{\frac{1-\eta}{B}} - \varepsilon_L^{\frac{1-\eta}{B}}\right) + (\varepsilon_H - \varepsilon_L)\left(\varepsilon_H^{\frac{1-\eta}{B}} + \varepsilon_L^{\frac{1-\eta}{B}}\right)
\]

\[
= \frac{2}{\varepsilon_H^{\frac{1-\eta}{1-B}} + \varepsilon_L^{\frac{1-\eta}{1-B}}} < 0.
\]
Hence (47) holds. Then we have established that $\theta_2 > \theta^*$. ■

**Competitive Search:** The Lagrangian for (38) is

$$\mathcal{L} = \frac{\alpha(n)}{n} A \{ (1 - \tau) \varepsilon_H [f(k_b + q) - f(k_b)] - z \}$$

$$+ \omega \{ \alpha(n) A z - \alpha(n) A \varepsilon_L (1 - \tau) [f(k_s) - f(k_s - q)] - v_s \} .$$

The FOC’s are

$$0 = \frac{\alpha(n)}{n} \varepsilon_H f'(k_b + q) - \lambda \alpha(n) \varepsilon_L f'(k_b - q)$$

$$0 = \frac{\alpha(n) - n \alpha'(n)}{n^2} \left[ \varepsilon_H f(k_b + q) - \varepsilon_H f(k_b) - \frac{z}{1 - \tau} \right]$$

$$+ \lambda \alpha'(n) \left[ \frac{z}{1 - \tau} - \varepsilon_L f(k_s) + \varepsilon_L f(k_s - q) \right]$$

$$v_s = \alpha(n) \left[ \frac{z}{1 - \tau} - \varepsilon_L f(k_s) + \varepsilon_L f(k_s - q) \right] .$$

Using (49) to eliminate $\omega$ from (50), we obtain

$$\frac{z}{1 - \tau} = \frac{e(n) \varepsilon_H f'(k_b + q) \varepsilon_L [f(k_s) - f(k_s - q)]}{e(n) \varepsilon_H f'(k_b + q) + [1 - e(n)] \varepsilon_L f'(k_s - q)}$$

$$+ \frac{[1 - e(n)] \varepsilon_L f'(k_s - q) \varepsilon_H [f(k_b + q) - f(k_b)]}{e(n) \varepsilon_H f'(k_b + q) + [1 - e(n)] \varepsilon_L f'(k_s - q)}$$

where $e(n)$ is the elasticity of the matching function.

Note that (52) says the payment $p = z$ is the same as as the outcome of Nash bargaining when buyer’s bargaining power is $\theta = e(n)$. Given this, $n$ and $q$ solve (51) and (52). DM value function is Because $V(z, k, \varepsilon_H) = v_b + W(z, k, \varepsilon_H)$, by the envelope theorem

$$V_1(z, k, \varepsilon_H) = \frac{\alpha(n)}{n} A \frac{\varepsilon_H f'(k + q) - \varepsilon_L f'(k - q)}{\varepsilon_L f'(k - q) + A}$$

$$V_2(z, k, \varepsilon_H) = - \frac{\alpha(n)}{n} A (1 - \tau) \left[ \varepsilon_H f'(k + q) - \varepsilon_H f'(k) \right]$$

$$+ A (1 - \tau) \left[ \varepsilon_L f'(k + 1 - \delta) \right] .$$

From the expression for $V(z, k, \varepsilon_L)$ we obtain

$$V_1(z, k, \varepsilon_L) = A$$

$$V_2(z, k, \varepsilon_L) = \alpha(n) \varepsilon_L A (1 - \tau) \left[ f'(k - q) - f'(k) \right]$$

$$+ A (1 - \tau) \left[ \varepsilon_L f'(k) + 1 - \delta \right] .$$
Then combine with the first-order conditions in the CM, we obtain (39) and (40).

**Proof of Proposition 9**: First, \( q \) is a continuous function of \( k \), \( q = Q (k) \) where

\[
Q' (k) = - \frac{f'' (k + q) f' (k - q) - f' (k + q) f'' (k - q)}{f'' (k + q) f' (k - q) + f' (k + q) f'' (k - q)}
\]

can be positive or negative depends on the sign of \( f'' (k + q) f' (k - q) - f' (k + q) f'' (k - q) \).

In addition, if \( k \to 0 \), \( Q (k) \to 0 \) and if \( k \to \infty \), \( Q (k) \to \infty \) and \( k - Q (k) \to \infty \).

Equation (40) defines \( k \) as a continuous function of \( q \): \( k = K (q) \). Notice that \( K (0) = k_0 \) where \( k_0 \) solves

\[
\frac{r + \delta}{1 - \tau} = (\gamma_H \varepsilon_H + \gamma_L \varepsilon_L) f' (k_0).
\]

If \( q \to \infty \), \( K (q) \to \infty \) and \( K_2 (q) - q \to c < \infty \) where \( c \) solves

\[
\frac{r + \delta}{1 - \tau} = \alpha (n) \gamma_L \varepsilon_L f' (c).
\]

Any \( k \) that satisfies \( K \circ Q (k) - k = 0 \) is an equilibrium. Notice \( K \circ Q (0) = k_0 > 0 \).

In addition, if \( k \to \infty \)

\[
K \circ Q (k) - k = K \circ Q (k) - Q (k) + Q (k) - k \to c - \infty.
\]

This means that \( K \circ Q (k) - k < 0 \) for \( k \) sufficiently large. By the intermediate value theorem, an equilibrium exists. At the equilibrium \( k \) and \( q = Q (k) \),

\[
\frac{\partial}{\partial k} [K \circ Q (k) - k] = K' \circ Q (k) Q' (k) - 1
\]

\[
\approx - \left\{ \gamma_H \left[ 1 - \frac{\alpha (n)}{n} \right] \varepsilon_H + \gamma_L \left[ 1 - \alpha (n) \right] \varepsilon_L \right\} f'' (k) \frac{\partial}{\partial k} f' (k + q) f' (k - q)
\]

\[
- 2 \frac{\alpha (n)}{n} \gamma_H \varepsilon_H f'' (k + q) \frac{\partial}{\partial k} f' (k + q) f' (k - q).
\]

Since all terms are negative, \( K' \circ Q (k) Q' (k) - 1 < 0 \). In this case, \( K \circ Q (k) - k = 0 \) for at most one \( k \) and uniqueness follows. ■
